The role of enteroviruses in gastrointestinal disease is unsettled but probably is minor. Conflicting data comparing rates of enterovirus isolation from children with acute diarrheal illness and matched healthy control subjects are reported. Some echoviruses, particularly types 11, 14 and 18, have been implicated in outbreaks of diarrhea in young infants. Enteroviral hepatitis beyond the neonatal period occurs rarely.[97,98] Pancreatitis is reported in patients infected with group B coxsackievirus types 1 to 5 and echovirus types 6, 11, 22, and 30. Prospective studies of acute pancreatitis have demonstrated concurrent enterovirus infection in 2% to 20% of patients.[99,100] Orchitis can occur in adolescents during infection with coxsackievirus A9, group B coxsackieviruses 2, 4, and 5, and echovirus 6.

Enteroviruses and Diabetes Mellitus

Although the role of genetic susceptibility is clearly established, enterovirus infection may initiate and possibly maintain an inflammatory insult to pancreatic islet cells and thereby contribute to the development of type 1 diabetes mellitus.[101] Evidence for the involvement of group B coxsackieviruses is most abundant, but other species B and C enteroviruses also are implicated.[102–105] Cases of new onset diabetes occur in seasonal patterns,[106,107] and sometimes in clusters or small outbreaks, often peaking 1 to 2 months after peak enterovirus activity.[108,109]

Two major theories of the pathophysiology of enterovirus-induced diabetes have been proposed. The “direct hit” hypothesis posits destruction of pancreatic islets by direct viral infection. A second theory focuses on acute viral infection as a trigger for an autoimmune response to pancreatic islet cells because of the similarity between the antigens of the virus and islet cells.[110] Although persistent enterovirus infection also is considered a possible mechanism of islet cell damage, evidence of persisting infection in immunocompetent humans is inconsistent and controversial.[101,109,111,112]

Infection in Special Hosts

Infections in Pregnancy

Nonpolio enterovirus infections do not appear to be more serious in pregnant women, although a distinctive syndrome of fever and severe abdominal pain (probably secondary to mesenteric lymphadenitis) is described in late pregnancy in association with perinatal transmission to neonates.[113,114] Although enterovirus infection during pregnancy undoubtedly is common, documented intrauterine infection is rare, perhaps because of an effective placental barrier.[10,115] Rare cases of fetal hydrops and stillbirth are reported,[116] but evidence that fetal infection is associated with congenital malformation is speculative.

Neonatal Infections

Neonates are at risk of serious, often fatal disease resulting from enterovirus infections acquired during the perinatal period. The echoviruses and group B coxsackieviruses are responsible for most neonatal infections, especially echovirus serotypes 6, 9, and 11 and group B coxsackievirus serotypes 1 to 5. Serious neonatal group B coxsackievirus serotype 1 disease was widely reported during 2007 and 2008 when this serotype circulated prominently in the US.[117] Parechoviruses, especially parechovirus serotype 3, are reported to cause neonatal encephalitis, severe hepatitis, rash with fever, and other neonatal syndromes identical to those caused by enteroviruses.[118]

Neonates who acquire enterovirus infections perinatally as a result of vertical transmission from infected mothers develop illness within the first week of life. Onset of serious infection beyond 10 days of age is rare. During seasonal outbreaks, approximately 3% of pregnant women excrete enteroviruses at term.[10] The outcome of neonatal infection is strongly influenced by the presence or absence of passively acquired maternal antibody specific for the infecting enterovirus serotype.[10,119,120] Thus the timing of maternal infection in relation to delivery is probably the most critical factor in the outcome of neonatal enterovirus infection.

Horizontal transmission from family members and nosocomial postnatal infection occur less frequently.[114,121,122] Infant-to-infant spread within nurseries occurs via the hands of healthcare personnel engaged in mouth care, gavage feeding, and other activities affording close direct contact.[123]

Although a wide range of clinical disease has been reported in neonates, including benign nonspecific febrile illnesses, exanthems, and aseptic meningitis, the most severe manifestations include myocarditis, hepatitis, encephalitis, and pneumonia.

Myocarditis

Neonatal myocarditis is most frequently caused by group B coxsackievirus serotypes 2 to 5. The onset often is abrupt, with respiratory distress, tachycardia, cyanosis, jaundice, and diarrhea. Initial examination frequently reveals temperature instability, tachycardia, arrhythmia, hepatomegaly, and signs of poor peripheral circulation. ECG tracings can show low-voltage and other electrophysiologic abnormalities, and echocardiograms often indicate poor left ventricular or biventricular function.

Approximately one third of illnesses are biphasic, with lethargy, poor feeding, or mild respiratory distress preceding the onset of cardiac manifestations by 2 to 5 days.

Infants with group B coxsackievirus myocarditis often have concomitant meningoencephalitis, pneumonia, hepatitis, pancreatitis, or adrenalitis. Although a limited number of organs can be involved pathologically, the degree of involvement often is severe, thus giving rise to terms such as *disseminated, systemic,* or *overwhelming* group B coxsackievirus disease in the neonatal period. The mortality rate in infants with myocarditis alone is generally reported to be 30% to 50%, but it is higher when other organs are involved. Survivors may have gradual improvement in cardiac function, whereas others have chronic impairment.

Hepatitis

Neonatal hepatitis can occur as the sole manifestation of infection or can accompany myocarditis and other manifestations of neonatal group B coxsackievirus disease. Echovirus 11 has been implicated most frequently,[114] but cases caused by echovirus serotypes 6, 7, 9, 14, 17, 19, and 21 and group B coxsackieviruses are described. The degree of hepatic involvement varies, but a severe form of hepatitis unique to this age group is characterized by extensive necrosis of the liver and fulminant hepatic failure. Initial signs and symptoms of severe hepatitis resemble those of septicemia, with lethargy, poor feeding, apnea, and jaundice. Within 2 to 3 days, evidence of hypocoagulability appears, along with ecchymoses and prolonged bleeding at puncture sites. Anemia, marked prolongation of the prothrombin time and partial thromboplastin time, and extreme elevations of serum transaminase levels occur.[113,114] Marked hypocoagulability, more attributable to hepatic failure than to disseminated intravascular coagulation, causes spontaneous hemorrhage into the skin, lungs, gastrointestinal tract, kidneys, and brain. The mortality rate is high. Infants dying of hepatitis have massive hepatic necrosis (Fig. 236.3) and may have extensive hemorrhage into the cerebral ventricles, pericardial sac, renal medulla, and interstitial spaces of many solid organs. Necrosis commonly is limited to the liver and adrenal glands and spares the heart, brain, meninges, and other organs. Cirrhosis and chronic hepatic insufficiency can develop in some survivors, whereas other survivors recover hepatic function.

Central Nervous System Infection

Extreme lethargy, seizures, hemiparesis, flaccid paralysis, and coma herald the more serious form of meningoencephalitis that occurs in the neonate as isolated CNS disease or accompanying myocarditis or hepatitis. Inflammation of the brain or spinal cord is found in approximately two thirds of infants dying of myocarditis.[124] Distinctive periventricular white matter lesions have been observed by magnetic resonance imaging in many neonates with enterovirus (and parechovirus) encephalitis, and postmortem microscopic examination demonstrates diffuse or scattered perivascular inflammation with lesions in the cerebrum, cerebellum, pons, medulla, and spinal cord.[125,126] Survivors can have residual cognitive and motor deficits.

Pneumonia

Echovirus serotypes 6, 9, and 11 have been associated with a few reported cases of perinatal pneumonitis.[127] Some cases characterized by the onset of symptoms within hours of birth suggest prenatal exposure and have a high mortality rate. Less severe neonatal pneumonitis has been described with echovirus serotypes 7 and 22.[128] Pathologic evidence of pneumonitis can be seen with group B coxsackievirus myocarditis in newborns, but generally it is limited to focal areas of interstitial inflammation.[124]

Infections in Patients With Immunodeficiency

Enteroviruses cause persistent, sometimes fatal infections of the CNS, gastrointestinal tract, and skeletal muscle in patients with hereditary or acquired defects in B-lymphocyte function. Most reported patients are children with X-linked agammaglobulinemia or severe combined immunodeficiency syndrome[14] or adults with common variable immunodeficiency. Cases of chronic meningoencephalitis as a complication of X-linked hyper-IgM syndrome and in children treated with anti-CD20 monoclonal antibody have been reported.[129] Severe multisystem or chronic infections also occur in recipients of bone marrow and solid organ transplants.[130] Echoviruses are responsible for most of these infections; individual cases caused by group A coxsackievirus types 4, 11, and 15 and by group B coxsackievirus types 2 and 3 have been reported.[14]

Chronic meningoencephalitis, the most common clinical syndrome, typically begins insidiously with headache, lethargy, mild meningismus, motor dysfunction, or seizures; abnormalities fluctuate in severity, disappear, or slowly progress. Persistent CSF pleocytosis and a high CSF protein concentration are characteristic. Virus is recovered persistently in high titer from the CSF of many patients.[14] Subtle abnormalities such as developmental arrest or regression are not uncommon, especially in IGIV-treated patients, and polymerase chain reaction (PCR) rather than culture can be necessary to confirm the presence of virus in CSF in such patients.[129,131]

Chronic myositis in a subset of hypogammaglobulinemic patients produces an illness similar to dermatomyositis. Recovery of virus from muscle tissue in at least 1 case suggested ongoing viral replication.[132] Isolation of enteroviruses from other tissues such as the brain, lung, liver, spleen, kidney, and bone marrow has suggested that infection is widely disseminated in at least some cases.

The prognosis for immunodeficient children who are persistently infected is poor. The efficacy of IGIV in the treatment of chronic enterovirus meningitis has been inconsistent. Some patients have experienced clinical improvement when IGIV was injected directly into the ventricles,[132] but relapse of infection occurs even after longterm intraventricular IGIV therapy. Pleconaril therapy has been used under compassionate release.[133,134]

Parechovirus Infections

Of the 14 parechovirus serotypes recognized to infect humans[135]; serotypes 1 and 3 are most commonly associated with disease.[136] The manifestations of parechovirus infections in infants are similar to those of enterovirus infections and are difficult to differentiate based on clinical presentation.[118] Parechoviruses commonly cause high persistent fevers in infants less than 5 months of age,[137,138] and they can be associated with a sepsis-like presentation.[139–141] Maculopapular exanthem is common, and a distinctive rash involving the extremities with palmar and plantar erythema has been noted with parechovirus 3 infection.[142,143] CNS infection, including aseptic meningitis and encephalitis associated with white matter changes, has been described in neonates.[125,126] Mild elevation in liver enzymes is common, and frank hepatitis with hepatic necrosis in newborns has been reported.[139] Absolute leukopenia can be a distinctive laboratory feature.[138] Parechoviruses follow a seasonal distribution similar to that of enteroviruses in temperate climates, predominating in the late summer to early fall.[144] A biannual pattern of parechovirus 3 infection has been noted in Europe since 1988.[144]

Laboratory Diagnosis

Polymerase Chain Reaction Testing

PCR detection of enteroviruses using primers that identify conserved sequences in the 5′ noncoding region of the enterovirus genome is more sensitive than culture in CSF, respiratory tract secretions, serum, and urine.[21,145,146] PCR also has been used to detect enteroviral RNA in cardiac tissue from patients with myocarditis,[89] although the relative sensitivity and specificity of the technique in these patients are not defined. PCR testing of fecal specimens can be adversely affected by polymerization inhibitors in stool. Many multiplex PCR assays commercially available for evaluation of respiratory specimens cannot differentiate rhinoviruses from enteroviruses because of their genetic similarities. Type-specific major capsid protein VP1 seminested PCR amplification and sequencing[147] or type-specific real-time (RT-PCR) can be used to identify specific enterovirus serotypes (e.g., enterovirus serotypes D68 and A71).[148]

Diagnosis of enterovirus meningitis by PCR of CSF has been shown to be more sensitive than cell culture and produces a faster result, thus enabling a shorter length of hospital stay.[149,150] PCR testing of serum, pharyngeal, and rectal specimens increases sensitivity,[151] but testing of pharyngeal and rectal specimens decreases specificity because it may detect asymptomatic shedding. The diagnosis of enterovirus A71 CNS disease often relies on virus detection by PCR in respiratory secretions or feces (or isolation of virus from these sites in cell culture) because the virus is uncommonly detected in CSF.[152]

Parechoviruses are not detected by PCR using typical enterovirus primers. However, PCR detection of all known human parechoviruses is possible using primers that identify conserved sequences in the 5′ untranslated region of the parechovirus genome. Parechovirus serotypes can be determined by nested or seminested PCR amplification and sequencing of the VP1 region[153] Because of similarities in clinical presentations requiring testing, combined human parechovirus-enterovirus RT-PCR assays have been developed.[154]

Virus Isolation

Isolation of viruses in cell culture remains an important method of laboratory diagnosis. Success of isolation varies widely between enterovirus classes and among serotypes within a class. Overall, sensitivity ranges between 50% and 75%. Generally, 3 or 4 primate cell lines must be used to support isolation of most enteroviruses. A cytopathic effect usually is evident between 2 and 5 days after the inoculation of cell monolayers. Once isolated, the virus serotype can be identified for most of the common enteroviruses with use of the Lim Benyesh–Melnick intersecting equine antiserum pools or by RNA sequencing. Group A coxsackieviruses do not grow in cell culture as readily as other enteroviruses; the optimal method for their isolation is newborn mouse inoculation.

An etiologic diagnosis is confirmed by isolation of virus from CSF, pericardial fluid, tissue, or blood. The opportunity to recover a virus in cell culture is optimized by sampling multiple sites. Isolation of virus from stool is less definitive because unrelated intercurrent asymptomatic infections and prolonged shedding can occur. However, because the background rate of shedding from the gastrointestinal tract is relatively low in the population, isolation of enterovirus from any site is presumptive evidence of disease causation.

Serologic Examination

The microneutralization test is the method used most widely for determining enterovirus antibodies. This serotype-specific assay has limited usefulness in the routine diagnosis of nonpolio enterovirus infections because it is not feasible to incorporate all relevant viral antigens into the assay, and methods based on neutralization are relatively insensitive, poorly standardized, and labor intensive. Type-specific immunoassays now are available commercially for measuring antibodies against the more common enterovirus serotypes, but they often are not well standardized. Serum IgM antibody has been detected early in the course of infection with group B coxsackieviruses, echovirus 30, and enterovirus D70. However, enteroviral IgM assays are not generally serotype specific,[151,155] and they appear to lack sensitivity.[156]

Antigen detection assays using monoclonal antibodies have been developed to identify specific serotypes such as enterovirus A71.

Treatment

Immune serum immunoglobulin and IGIV are reported to suppress or eradicate persistent enterovirus infections in some, but not all, patients with immunoglobulin deficiency or other immunodeficiencies.[14] However, the efficacy of immunoglobulin has not been demonstrated in the treatment of other serious or acute enterovirus infections. A prospective, randomized trial of IGIV (750 mg/kg) for treatment of enterovirus infections in newborn infants did not demonstrate significant clinical benefit, nor did this treatment reduce the daily incidence of viremia or viruria overall; however, viremia and viruria remitted faster among subjects who received IGIV that contained a neutralization titer of ≥1 : 800 to the subject's infecting virus.[157] IGIV (with or without corticosteroids) has been used for patients with enterovirus A71 brainstem encephalitis; modulation of cytokine profiles has been shown, but data proving clinical efficacy are lacking.[158] High-titer enterovirus A71 immune globulin is being evaluated. IGIV may have beneficial immunomodulatory effects in enteroviral myopericarditis.[159] In a study using historical controls, improved cardiac function and a trend toward increased survival was found in children with acute myopericarditis who were treated with IGIV.[160] However, randomized controlled trials have not been reported. Although corticosteroid and other immunosuppressive therapies have been used for myocarditis,[161,162] experimental evidence suggested adverse rather than beneficial effects,[163] and a large prospective randomized trial of prednisone combined with either cyclosporine or azathioprine versus supportive treatment showed no differences in outcome.[164]

Antiviral compounds in clinical development include agents that bind avidly to a pocket in the viral capsid, thereby preventing virus attachment and uncoating.[165] One compound, pleconaril, an orally administered drug with a favorable pharmacokinetic and toxicity profile, was studied in clinical trials and was shown to have a modest benefit in adults and children with enterovirus meningitis and picornavirus upper respiratory tract infections.[166–169] Uncontrolled experience in immunocompromised patients with persistent enterovirus infections and patients with serious, potentially fatal infections also indicated possible clinical benefit.[62,133,170] A randomized, placebo-controlled, phase II trial of pleconaril orally for treatment of neonates with enteroviral sepsis syndrome suggested possible virologic and clinical efficacy.[171] Unfortunately, although new drugs are in development, no antiviral agents are currently available in the US.[172]

Prevention

Because pre-exposure administration of immune serum globulin reduces the risk of paralytic poliomyelitis, it is possible that nonpolio enterovirus infections could be prevented in the same manner. Although commercial preparations of IGIV contain variable concentrations of antibody against some enterovirus serotypes, no data are available regarding the protective efficacy of these preparations. Prophylactic administration of immune globulin (or convalescent plasma) has been attempted in the setting of nursery epidemics, but the use of infection control strategies confounds interpretation of efficacy. Maintenance administration of IGIV in hypogammaglobulinemic patients has reduced the incidence of chronic enteroviral meningoencephalitis, although breakthrough infections occur. Active immunization against the nonpolio enteroviruses as a group is not practical because of the large number of serotypes. However, several candidate enterovirus A71 vaccines have been developed that were effective against HFM disease and herpangina in clinical trials, with suggested protection against neurologic disease.[173,174]

Simple hygienic measures such as handwashing, careful disposal of soiled diapers, and avoidance of shared eating utensils and drinking containers should reduce transmission. It is prudent to advise pregnant women and children who are immunocompromised to avoid contact, whenever possible, with people suspected of having enterovirus infection.

Hepatitis A Virus

Melissa G. Collier, Noele P. Nelson

Pathogen

Hepatitis A virus (HAV) is a nonenveloped RNA virus and a member of the Picornaviridae family.[1] The single-stranded RNA genome is approximately 7500 nucleotides long and contains a single, long, open reading frame. The encoded polyprotein includes structural proteins for the 27- to 28-nm diameter capsid, nonstructural proteins with protease or polymerase activities, and other proteins with functions that have not been fully determined.[2,3]

Among infected people, HAV replicates in the liver, is excreted in bile, and is found in high concentrations in stool. The incubation period averages 28 days (range, 15–50 days). Peak viral concentrations in stool and greatest infectivity are during the 2 weeks before the onset of symptoms. Virus concentrations in stool diminish markedly within 1 week after the onset of symptoms. However, polymerase chain reaction assays have been used to demonstrate low levels of viral RNA in stools of infected neonates for up to 6 months after infection.[4] In older children, HAV RNA can be detected in stools for as long as 10 weeks after symptoms begin, but the clinical significance of these findings is uncertain.[5] Viremia occurs soon after infection and persists at least through the period of elevation of hepatic enzymes in serum.[6,7]

The pathogenesis of HAV infection is not completely understood. However, the absence of cytopathic changes in cell culture and the demonstration of HAV-directed natural killer and lymphokine-activated killer cells in vitro suggest that cell-mediated immunity is responsible for hepatocellular damage.[8]

HAV is a single serotype.[9] Seven HAV genotypes have been identified with unique geographic distribution; 4 genotypes are found in humans (I, II, II, IV).[3] Genotype IA is the most commonly identified genotype in US HAV cases (88%), followed by IB (11%) and IIIA (0.7%).[10]

Immunity resulting from HAV infection is lifelong. In contrast to infection with hepatitis B and hepatitis C viruses, HAV infection does not result in chronic infection or chronic liver disease.

Epidemiology

The principal mode of HAV transmission is from person to person, by the fecal-oral route. Transmission occurs most commonly among close contacts, including household and sexual contacts of people infected with HAV. HAV also is transmitted by contaminated food, most often from an infected food handler, but also in association with food contaminated before retail distribution (e.g., produce contaminated during growing or processing).[11–13] Common-source food exposures are of increasing concern. Several outbreaks of hepatitis A virus genotype IB illness associated with food from the Middle East have been reported, including frozen strawberries from Egypt and Morocco in Europe, frozen pomegranate seeds from Egypt in Canada, semidried tomatoes from Turkey in Europe and Australia, and pomegranate arils from Turkey in the United States.[14–19] Transmission by contaminated water is rare. Because transient viremia occurs in HAV infection, bloodborne HAV transmission can occur, such as among injection drug users.[20] On rare occasions, HAV infection has been transmitted by transfusion of blood or blood products collected from donors during the viremic phase of infection.[21] In addition, outbreaks have been reported in Europe and the US among patients who received factor VIII and factor IX concentrates prepared with the use of solvent detergent treatment.[22] However, changes in viral inactivation procedures, introduction of hepatitis A vaccine, and improved donor screening have nearly eliminated the risk for HAV transmission from clotting factors.[23] Vertical transmission to children from pregnant women who develop hepatitis A during the third trimester of pregnancy has been reported, but the risk appears to be low. In approximately 50% of people with sporadic, community-acquired hepatitis A, no source of infection is identified.[24] When a risk factor is identified, international travel is the most commonly reported.[10,25]

Because most young children have asymptomatic or unrecognized infections, they play an important role in the epidemiology of hepatitis A and often serve as sources of infection for others. In several studies using serologic testing of household contacts, 25% to 40% of contacts <6 years of age had serologic evidence of acute HAV infection.[26,27] In 1 US study, 52% of households of adults without an identified source of infection included a child <6 years of age, and the presence of a young child was associated with HAV transmission in the household. In this study, transmission chains were identified that involved as many as 6 generations and >20 cases.[26]

The relationship between risk of infection and likelihood of asymptomatic infection during childhood is important to understanding HAV transmission patterns worldwide and to developing prevention strategies. Level of economic development, as indicated by hygienic and sanitary conditions, is correlated with global HAV transmission patterns (Fig. 237.1). In areas where seroprevalence of antibody to HAV (anti-HAV) is high even among young children (e.g., parts of Asia, Africa, Central and South America), the lifetime risk of infection is greater than 90%, and infection occurs primarily in early childhood.[27,28] Asymptomatic infection predominates, and nearly the entire population is infected before reaching adolescence. The high rates of HAV transmission during childhood may not be recognized because typical clinical manifestations of hepatitis A are uncommon in children. The incidence of clinical hepatitis A generally is low, and outbreaks are rare because most adults are immune. However, adults who remain susceptible to infection in these areas are at high risk for HAV infection. Travelers to highly endemic areas from the developed world also are at high risk. In areas of moderate endemicity (e.g., Eastern Europe), HAV is not transmitted as readily because of better sanitation and living conditions, and the average age of infection is older than in areas of high endemicity. However, transmission among young children remains relatively common. Paradoxically, the potential for large outbreaks can be increased (compared with highly endemic areas) because of the relatively larger pool of susceptible older children and adults who are at high risk for infection and who, when infected with HAV, are likely to develop symptomatic illness.[29] Unimmunized travelers from the developed world to these areas also are at risk.[30] In some instances, countries undergoing rapid development accompanied by improvement in sanitation standards and clean water supplies have experienced changes in the epidemiologic pattern of HAV. In these countries, HAV is likely to become a more serious problem.[31] Declines in childhood and adolescent HAV seroprevalence lead to susceptibility at a later age, with greater associated morbidity and mortality. In most developed countries without universal vaccination policies, the incidence of both HAV infection and hepatitis A clinical disease is low. Most cases occur in the context of cyclic, community-wide outbreaks that feature transmission among preschool and school-aged children and their adult contacts.[31] As endemicity continues to decline in some parts of the developed world, most cases are identified in defined risk groups, such as travelers returning from endemic areas, international adoptees from endemic countries, and injection drug users.[29,32]

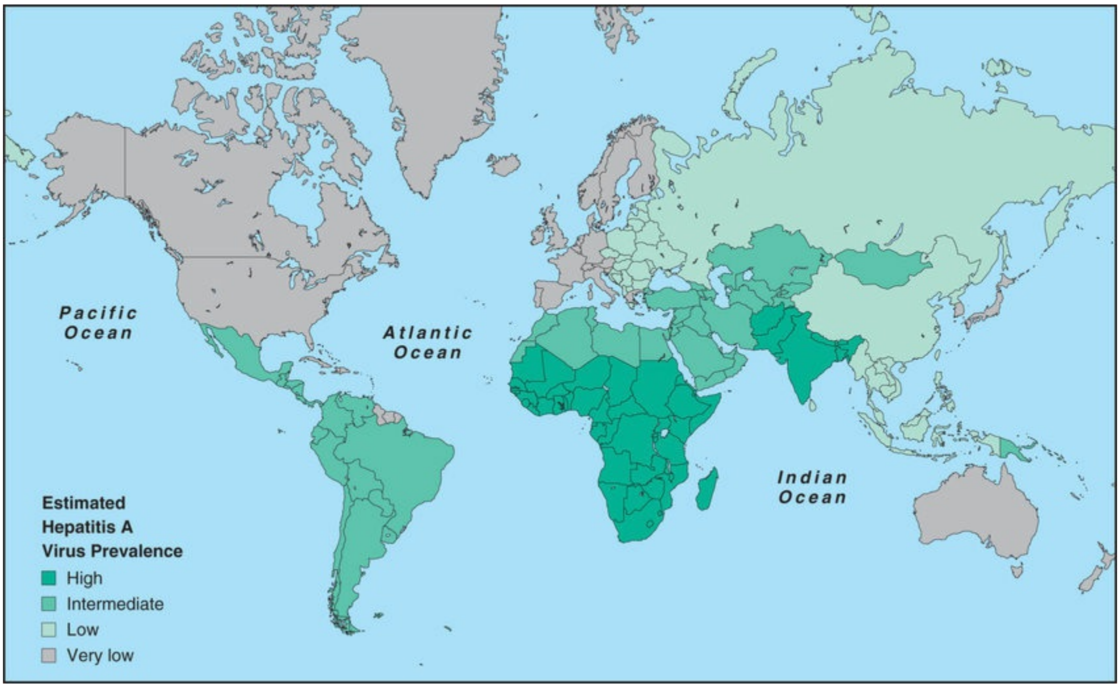

FIGURE 237.1 **Prevalence of antibody to hepatitis A virus, 2006. Geographic distribution of hepatitis A virus (HAV) infection endemicity. For multiple countries, estimates of prevalence of antibody to hepatitis A virus (anti-HAV), a marker of previous HAV**

infection, are based on limited data and may not reflect actual prevalence. In addition, anti-HAV prevalence rates could vary within countries by subpopulation and locality. (Adapted from Jacobsen KH, Wiersma ST. Hepatitis A virus seroprevalence by age and world region, 1990 and 2005. Vaccine 2010;28:6653–6657.)

In the US, before hepatitis A vaccine was widely available, hepatitis A occurred in large, nationwide epidemics approximately every decade.[25] Until 2001, the highest rates of HAV infection in the US were observed among children 5 to 14 years of age, with approximately one third of reported cases involving children <15 years of age.[33–35] The highest rates and the majority of cases occurred in the western and southwestern states.[34–36]

Since licensure of the first hepatitis A vaccines in 1995, incidence rates have declined sharply (Figs. 237.2 and 237.3).[25] Declines have been especially prominent since implementation of targeted recommendations made in 1996 to 1999 for childhood vaccination in states with high hepatitis A rates.[33,34] In 2006, universal vaccination was recommended in all states.[28] The number of reported cases in the US reached an all-time low of 1398 cases in 2011, thus representing a 96% decline in reported cases since vaccine recommendation. The first increases in cases since 1995 occurred in 2012 (1562 total cases) and again in 2013 (1781 total cases), coincident with the 2013 multistate outbreak of hepatitis A.[19,25,37] The number of cases increased slightly in 2014 (1239 cases). Hepatitis A rates declined since vaccine introduction from 11.7 cases per 100,000 population in 1996 to 0.4 cases per 100,000 population in 2011, with a slight increase to 0.5 and 0.6 cases per 100,000 population in 2012 and 2013, respectively, and declined in 2014 back to 0.4 cases per 100,000 population.[25,37] Since the mid-2000s, age, regional, ethnic, and racial differences in incidence rates of hepatitis A have been eliminated, thereby indicating fundamental shifts in hepatitis A epidemiology (see Fig. 237.3).[24,38,39] Moreover, with the lack of circulating HAV after massive declines in HAV infections among children, the seroprevalence rates have dropped for adults as the average ages of hepatitis A hospitalizations and deaths have increased.[40] The likely reason for this finding is that the adults who were infected in childhood with subsequent immunity are aging out of the population, to be replaced by adults who were too old to be vaccinated as children but who did not have the opportunity to be exposed to the virus and develop disease at an earlier age. The 2013 multistate outbreak of hepatitis A occurred largely in adults, with few cases in unvaccinated children.[38] This finding illustrates that future problems with imported food contaminated with HAV may pose a risk to this large, susceptible, adult population.

Methods to isolate and sequence HAV from sera of infected people and to define the genetic variation of HAV are advancing understanding of the epidemiology.[41] The resulting database of HAV genome sequences has been useful in investigations of foodborne outbreaks by demonstrating links among apparently sporadic cases and suggesting possible sources of contamination.[11,38,42]

Clinical Manifestations

HAV infection can be inapparent (the patient is asymptomatic with no elevation in serum hepatic enzymes), subclinical (asymptomatic with elevation of hepatic enzymes), anicteric (symptomatic without jaundice), or icteric (symptomatic with jaundice). The likelihood of having symptoms with HAV infection is related directly to age. Most children <6 years of age have asymptomatic infection or mild, nonspecific symptoms with hepatitis A; <10% of children in this age group have jaundice.[43] Among older children and adults, 76% to 97% have symptoms when they are infected with HAV, and 40% to 70% of patients with symptoms are icteric.[44]

When symptoms occur, most patients have an onset of low-grade fever, myalgia, anorexia, malaise, nausea, and vomiting. These symptoms are followed several days later by specific symptoms and signs of hepatic dysfunction, including dark urine, light-colored stools, jaundice, and scleral icterus.[44] Many children (60%) and some adults (20%) have diarrhea. Some children (<20%) have upper respiratory tract symptoms (e.g., cough, coryza, sore throat). Urticaria can occur at the onset of illness.[45] Physical findings are variable and can include jaundice, scleral icterus, hepatomegaly, right upper quadrant tenderness, and splenomegaly. Abdominal ultrasonography showed edema of the gallbladder wall in approximately 50% of children with uncomplicated hepatitis A who were studied prospectively; transient ascites occurred in a few patients.[46] The symptoms of hepatitis A last for several weeks on average and usually not longer than 2 months, although some people can have prolonged or relapsing signs and symptoms for up to 6 months.

Laboratory Findings and Diagnosis

During HAV infection, inflammation of the liver is accompanied by abnormalities in serum hepatic enzymes, with increases in serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, and γ-glutamyltranspeptidase. Usually in acute hepatitis A, ALT and AST values are between 200 and 5000 IU/L; the ALT value is higher than the AST value; and alkaline phosphatase levels are only mildly elevated. Elevations in ALT and AST can precede symptoms by a week or more and generally peak 3 to 10 days after the onset of symptoms (Fig. 237.4).

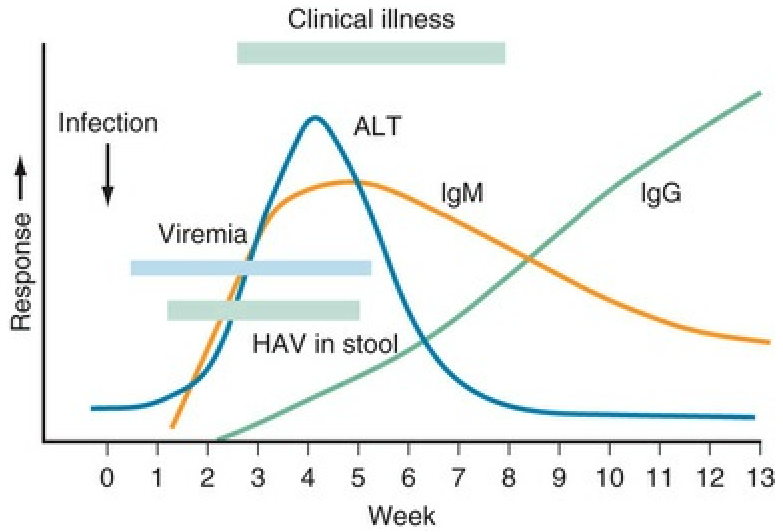

FIGURE 237.4 **Typical serologic profile of hepatitis A virus (HAV) infection. ALT, serum alanine aminotransferase level; Ig, immunoglobulin.**

The specific diagnosis of hepatitis A relies on serologic testing in addition to the presence of symptoms. Virtually all people with acute hepatitis A have detectable immunoglobulin (Ig) M anti-HAV during the acute or early convalescent phase of infection (see Fig. 237.4).[47] IgM anti-HAV generally disappears within 6 months after the onset of symptoms, although people who test positive for IgM anti-HAV >1 year after infection or with no known history of infection have been reported.[48,49] IgG anti-HAV, which appears in the convalescent phase of infection, remains detectable in serum for the person's lifetime and confers protection against disease. Commercial enzyme immunoassays are available for detection of

IgM and total anti-HAVs in serum. Because the test for total anti-HAVs frequently is performed first in laboratories, and results are positive for anyone who has been vaccinated or infected in the past, IgM anti-HAV detection is necessary to make the diagnosis of HAV hepatitis.

Polymerase chain reaction assays can be used to detect HAV RNA in stool specimens and sera of people with HAV infection, although these tests are available only in a few research laboratories.[3,6] To date, polymerase chain reaction assays cannot determine whether a person is infectious because incomplete virus particles can be detected. On the basis of epidemiologic studies, peak infectivity occurs during the 2 weeks before the onset of symptoms. For practical purposes, people with hepatitis A can be assumed to be noninfectious 1 week after the onset of jaundice.

Light microscopic examination of liver specimens in acute hepatitis A reveals pathologic features common to all forms of viral hepatitis, including hepatocellular necrosis, inflammatory infiltration of lymphocytes and other mononuclear cells, and regeneration of hepatocytes. The extent of involvement varies with the stage and severity of hepatitis and age of the patient. Liver biopsy typically is not indicated for the diagnosis or management of hepatitis A.

Treatment

Treatment generally is supportive. Hospitalization may be necessary for patients who are dehydrated from nausea and vomiting or who have fulminant hepatitis A. No specific diet or restriction of activity is necessary. Medications that can cause hepatic damage or that are metabolized by the liver should be used with caution. For the infrequent presentations of cholestatic or relapsing hepatitis A, a short course of corticosteroid therapy has been reported as effective in limiting symptoms and hastening recovery, but no controlled trials have evaluated this approach.[50,51]

Liver transplantation is successful in some people with acute liver failure. Criteria for choosing patients for liver transplantation are difficult to establish because survival without transplantation is high (50%–70%), even for patients in a coma, and no single factor is predictive of a poor outcome.[52]

Special Considerations

HAV infection occasionally results in fulminant hepatitis and death. In addition, hepatitis A has several atypical manifestations, including relapsing hepatitis A, cholestatic hepatitis, autoimmune hepatitis, and extrahepatic symptoms.

Fulminant hepatitis A, characterized by the onset of severe liver injury and hepatic encephalopathy in patients with no known preexisting liver disease, is an infrequent occurrence.[53] The case-fatality rate among reported cases of hepatitis A in all age groups is approximately 0.6%.[25] Host factors associated with a higher risk for fulminant hepatitis A include older age (>50 years old) and underlying chronic liver disease.[54] Molecular studies have not shown an association between fulminant hepatitis A and any type of viral variant. Of 348 children with acute liver failure from the US, Canada, and the United Kingdom who were entered into a registry, only 3 (0.9%) had acute hepatitis A.[55] Spontaneous recovery occurs in 30% to 60% of people with fulminant HAV infection, and survivors generally regain full liver function. Prognosis is influenced by age, clotting factor level, stage of coma, and presence of renal disease.[24] In approximately 10% to 15% of patients with hepatitis A, relapsing hepatitis occurs, and approximately 20% of these patients have multiple relapses.[24,51] These patients typically have another episode of hepatitis 1 to 4 months after the initial acute hepatitis. The relapse is accompanied by elevation of serum hepatic enzymes and persistence of IgM anti-HAV. Molecular studies have demonstrated the presence of HAV in stool specimens during relapse. Most patients recover completely within several weeks.

Cholestatic hepatitis occurs rarely following infection with HAV.[50] Patients with this disorder have substantially elevated concentrations (>10 mg/dL) of bilirubin in serum and jaundice persisting for an extended period (in some cases >3 months). This syndrome can be distinguished from obstructive jaundice by normal abdominal ultrasonographic findings. A short course of corticosteroids can reduce symptoms and hasten disease resolution.[24]

Several case series have been described in which HAV infection is followed by autoimmune chronic active hepatitis, in some instances requiring longterm corticosteroid therapy.[56] Extrahepatic manifestations of hepatitis A include pruritus, arthralgia, cutaneous vasculitis, cryoglobulinemia, and hemophagocytic syndrome (anemia and thrombocytopenia, with hemophagocytosis apparent on biopsy of bone marrow). These manifestations are rare and resolve with resolution of hepatitis.

Prevention

The methods of prevention of hepatitis A include the following: (1) general measures of good personal hygiene (with an emphasis on hand hygiene), provision of safe drinking water, and adequate disposal of sanitary waste; and (2) pre-exposure or postexposure prophylaxis with immune globulin (IG) or hepatitis A vaccine.

Immune Globulin

IG is a solution of antibodies prepared from human plasma by serial ethanol precipitation for intramuscular administration. In the US, GamaSTAN (Grifols Therapeutics, Inc., Research Triangle Park, NC) is the only available hepatitis A immune globulin (IgG anti-HAV) product. The manufacturing process removes model enveloped and nonenveloped viruses, including human immunodeficiency virus, hepatitis B virus, and hepatitis C virus, as well as low levels of Creutzfeldt-Jakob disease (CJD)/variant CJD agent infectivity.[57] The efficacy of IG (0.02 mL/kg intramuscularly) in preventing hepatitis A is 80% to 90% when IG is administered before exposure to HAV or within 2 weeks after exposure.[58,59] Seroprotective anti-HAVs (i.e., 10–20 mIU/mL) appear rapidly after pre-exposure intramuscular injection and reach peak levels in approximately 2 days after injection.[59] No information exists regarding the efficacy of IG or vaccine if it is administered >2 weeks after exposure.[36] The prevalence of anti-HAV in the population has been declining; however, no clinical or epidemiologic evidence of decreased protection from IG has been observed, though decreased potency of IG has been found.[60,60a] IG is indicated in patients for whom the vaccine is contraindicated, and in certain situations for international travel and postexposure prophylaxis.[61]

IG should be administered intramuscularly only, preferably in the deltoid muscle of the upper arm or the anterolateral aspects of the upper thigh in children <24 months of age.[61] Serious adverse events from IG are rare. IG is contraindicated for patients with IgA deficiency because of reports of anaphylaxis in these people, as well as for patients who have severe thrombocytopenia or any coagulation disorder.[62] IG can be administered at the same time as most inactivated vaccines; however, IG can interfere with the response to live, attenuated virus vaccines (e.g., measles, mumps, and rubella vaccine and varicella virus vaccine) when administered either as individual or combination vaccines.[36,62,63]

Vaccine

Hepatitis A vaccine is preferred over IG for pre-exposure and postexposure prophylaxis because of induction of active immunity and longer protection, greater ease of administration, and often greater acceptability. In the US, HAVRIX (GlaxoSmithKline Biologicals, Philadelphia) was approved by the Food and Drug Administration in 1995 and VAQTA (Merck & Co. Inc., Whitehouse Station, NJ) was approved in 1996; both vaccines are licensed for people ≥12 months of age. In 2001, a combination hepatitis A and hepatitis B vaccine (TWINRIX, GlaxoSmithKline) was approved for patients 18 years old or older. Inactivated hepatitis A vaccines are prepared by methods including growth in cell culture, purification by ultrafiltration or other methods, inactivation with formalin, and adsorption to an aluminum hydroxide adjuvant.[64,65] HAVRIX and VAQTA are available in pediatric and adult formulations and are licensed in a 2-dose series, with the second dose scheduled 6 to 18 months after the first. However, if the second dose is given >18 months after the first dose, no additional doses are required.[63] The route of administration is intramuscular, in the anterolateral thigh for children aged <2 years and the deltoid muscle for children and adults. TWINRIX is licensed in a 3-dose series or a 4-dose alternate series.[66–68] Monovalent hepatitis A vaccine may be used to complete hepatitis A vaccination begun with TWINRIX and vice versa.[69]

Inactivated hepatitis A vaccines have been studied extensively in children and adults. In general, within 4 weeks after one dose of vaccine, ≥90% of children aged ≥1 year and adults respond with levels of antibody considered to be protective; a second dose is necessary 6 to 18 months later to boost antibody levels for longterm protection.[70,71] Nearly 100% of patients will develop protective antibodies after receiving 2 doses. Response to vaccine may be lower in patients >40 years of age, immunosuppressed patients, patients with advanced liver disease or recipients of liver transplants, and infants with passively acquired maternal antibody. Delayed administration of the second dose beyond 18 months does not appear to reduce immunogenicity.[72] Available data indicate that the vaccines are safe and immunogenic in children <12 months of age who do not have passively acquired maternal antibody.[73] However, final antibody concentrations in infants with passively acquired maternal antibody are one third to one tenth of those of anti-HAV–negative infants who are vaccinated according to the same schedule, and fewer infants with passively acquired maternal antibody have detectable anti-HAV 6 years after vaccination compared with children vaccinated as infants who did not have passively acquired maternal antibody.[73,74] The immunogenicity of TWINRIX is considered equivalent to that of the single antigen hepatitis vaccine when it is administered in a 3-dose series.[36]

Inactivated hepatitis A vaccine is highly efficacious in preventing clinical hepatitis A. In a large study conducted in Thailand among children 1 to 16 years of age, efficacy of the vaccine was 94% after 2 doses of vaccine administered 1 month apart.[75] In another study conducted in New York among children 2 to 16 years of age and with a different inactivated vaccine, efficacy was 100% starting 17 days after administration of 1 dose.[76]

The duration of protection after vaccination is unknown; however, anti-HAVs have been shown to persist in vaccine recipients for at least 20 years.[77–80] Detectable antibodies are estimated to persist for 20 to 25 years or longer, based on mathematical modeling and anti-HAV kinetic studies.[81,82]

In prelicensure clinical trials among children, the most frequently reported local reaction following hepatitis A vaccination was soreness at the injection site (15%–19%).[71,72] Systemic reactions that include fatigue, fever, diarrhea, and vomiting occurred in <5% of vaccine recipients.[36] No serious adverse events among children or adults that could be attributed definitively to the vaccine and no increases in serious adverse events among vaccinated people compared with baseline rates have been identified.[33,83,84]

In 1996, targeted hepatitis A vaccine was initially recommended by the Advisory Committee on Immunization Practices (ACIP) for children at 2 years of age and adolescents in communities with high rates of HAV disease or for outbreak control.[33] In 1999, the ACIP recommended vaccination in counties, communities, and 11 states with hepatitis A rates ≥20 cases per 100,000 population and consideration of vaccination in 6 additional states with rates of ≥10 cases but <20 cases per 100,000 population.[34] By 2004, first-dose coverage rates among children 24 to 35 months of age who were living in these states had reached 25% to 50%.[85] The impact of even limited routine vaccination of children on hepatitis A incidence was evidenced by historic reductions in incidence rates.[35,40] In 2006, the ACIP extended recommendations to routine vaccination of children 12 to 23 months of age and for anyone wishing to obtain immunity (Table 237.1).[36] Vaccination of people at increased risk for hepatitis A also is recommended (see Table 237.1 and Fig. 237.1).[36] In 2007, the ACIP updated recommendations for prevention of hepatitis A for international travel and postexposure prophylaxis.[61]

TABLE 237.1

Advisory Committee on Immunization Practices Recommendations for Routine Pre-Exposure Use of Hepatitis A Vaccine

Group	Comments
All children at 12–23 mo of age[a]	Integrate into routine childhood immunization schedule; children who are not vaccinated by 2 yr of age can be vaccinated at subsequent visits
Children 12–18 yr of age	Maintain existing programs[b]; can be considered in areas without existing programs
International travelers	Except people traveling to Canada, Western Europe, Japan, Australia, or New Zealand, who are at no greater risk than in the United States
Men who have sex with men	Includes adolescents
Illicit drug users	Includes adolescents
People with chronic liver disease	Increased risk of fulminant hepatitis A
People receiving clotting factor concentrates	
People who work with HAV in research settings	
Anyone wishing to obtain immunity	
People who anticipate close, personal contact (e.g.,	

household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity[c]	

[a]Hepatitis A vaccine is not licensed for children <12 months of age.

HAV, hepatitis A virus.

From Centers for Disease Control and Prevention. Prevention of hepatitis A through active or passive immunization: recommendations of the Advisory Committee on Immunization Practices. MMWR Recomm Rep 2006;55(RR-07):1–23.

In 2009, the ACIP updated guidance by recommending hepatitis A vaccination for all previously unvaccinated people who anticipate close personal contact with an international adoptee from a country of high or intermediate endemicity during the first 60 days following arrival of the adoptee in the US.[86]

The use of vaccine largely is responsible for the >95% decrease in hepatitis A cases since vaccine introduction from 1996 to 2011.[37] Geographic variability and most disparities in nationally reported acute hepatitis A disease by race or ethnicity have been eliminated.[35] However, 2-dose vaccine coverage remains low. Hepatitis A vaccine coverage for children 19 to 35 months of age in 2015 was 86% and 60% for ≥1 and ≥2 doses, respectively.[87] Coverage for children 13 to 17 years of age in 2012 was 60% and 48% for 1- and ≥2-dose coverage, respectively.[88] Among adults 19 to 49 years of age in 2014, a group for which vaccine is recommended only for those at high risk of HAV infection, the total ≥2-dose coverage was 12%; coverage was 19% for travelers outside the US and 18% for adults with chronic liver conditions.[89] Reduced exposure to HAV early in life, significant decreases in anti-HAV seroprevalence in older adults, and low 2-dose vaccination rates are causing an increasing proportion of susceptible adults.[19,89]

Sustained reduction in disease incidence in the US should be achieved through vaccination of successive cohorts of children and should provide the opportunity to eliminate HAV transmission. To achieve this goal, however, higher population vaccination coverage throughout the US must be achieved; rapid identification and control of outbreaks, including common-source food exposures, must continue; and expanded recommendations for single- or double-dose vaccination could be considered.

International Travel (Pre-exposure)

All susceptible people traveling to or working in countries that have high or intermediate hepatitis A endemicity should receive pre-exposure prophylaxis. Hepatitis A vaccine at the age-appropriate dose is preferred to IG for children and adults 1 to 40 years of age. One dose of a monovalent hepatitis A vaccine administered any time before departure protects most healthy people 1 to 40 years of age. No data on single dose hepatitis A vaccine efficacy are available for TWINRIX. For optimal protection, adults >40 years of age, immunocompromised people, and patients with chronic liver disease or other chronic medical conditions who are planning to depart to an area in <2 weeks should receive the initial dose of vaccine along with IG (0.02 mL/kg) administered at a separate injection site. Travelers who are <12 months of age, who are allergic to a vaccine component, or who otherwise elect not to receive vaccine should receive a single dose of IG (0.02 mL/kg), which provides effective protection against HAV infection for up to 3 months. Those who do not receive vaccination and who plan to travel for >2 months should receive an IG dose of 0.06 mL/kg, which must be repeated if the duration of travel is >5 months.[61]

Postexposure Prophylaxis

Hepatitis A vaccination has shown efficacy compared with placebo when it is given up to 14 days after exposure to a person with HAV infection.[61,90,91] A controlled study that compared the efficacy of hepatitis A vaccine with that of IG when given after exposure showed the performance of vaccine to be similar to that of IG in healthy children and adults 12 months through 40 years of age.[61,91] People who recently have been exposed to HAV and who previously have not received hepatitis A vaccine should be administered 1 dose of monovalent hepatitis A vaccine or IG (0.02 mL/kg) as soon as possible, ideally within 2 weeks of exposure. The relative efficacy of vaccine is comparable to that of IG for postexposure prophylaxis among people 1 to 40 years of age. For healthy people 1 to 40 years of age, a dose of monovalent hepatitis A vaccine is recommended. For people >40 years of age, IG is preferred, but vaccine can be used if IG is unavailable. IG is recommended for infants <12 months of age, people who are immunocompromised, patients with chronic liver disease, and people for whom vaccine is contraindicated.[61] TWINRIX is not approved for use as postexposure prophylaxis.

Key Points

Diagnosis and Management of Hepatitis A Virus Infection

Microbiology

- Nonenveloped RNA virus and member of the Picornaviridae family
- Replicates in the liver, is excreted in bile, and is found in high concentrations in stool
- Average incubation period of 28 days (range, 15–50 days)
- Greatest infectivity 2 weeks before onset of symptoms

Epidemiology

- Primarily fecal-oral transmission by person-to-person contact or consumption of contaminated food or water
- Endemic in many developing countries; infection occurs mainly in childhood.
- Low prevalence in developed countries; infection occurs typically among adolescents and adults.
- In the United States, international travel is the most frequently reported risk factor.
- International adoption is a risk factor.

Clinical Features

- Symptoms range from none to acute debilitating disease
- Symptomatic infection generally is characterized by acute onset and

- ▪ Early symptoms: low-grade fever, myalgia, anorexia, malaise, and vomiting.
- ▪ Later symptoms or signs: hepatic dysfunction, dark urine, light-colored stools, jaundice, and scleral icterus.

- Likelihood of developing symptoms increases with patient's age
- Average duration is 2 months; overall case-fatality rate is 0.3% to 0.6%

Diagnosis

- Presence of serum antibodies to HAV: IgM detectable 5 to 10 days before onset of symptoms; IgG appears in convalescent phase and is lifelong
- Polymerase chain reaction assay can be used to detect viral RNA in blood or stool but is not widely available and typically is used only in outbreak investigations.

Treatment

- Supportive care

Prevention

- General measures of good personal hygiene, provision of safe drinking water, and adequate waste disposal
- Pre-exposure or postexposure prophylaxis with hepatitis vaccine

or immune globulin

HAV, hepatitis A virus; Ig, immunoglobulin.

Rhinoviruses

Diane E. Pappas, J. Owen Hendley [†]

Rhinoviruses (*rhino*, nose) are the most common causes of the common cold, and they account for at least 50% of upper respiratory tract infections in children and adults. Rhinoviruses are difficult to detect, but the development of sensitive polymerase chain reaction (PCR)–based assays has led to the identification of 3 distinct groups of rhinovirus (*Human rhinovirus A* [HRV-A], *Human rhinovirus B* [HRV-B], and *Human rhinovirus C* [HRV-C]).[1] Although infection results in serotype-specific lasting immunity, rhinovirus infections are common because >100 different serotypes exist.

Description of Pathogen and Epidemiology

Rhinovirus belongs to the Picornaviridae family. The virus is composed of single-stranded RNA within a capsid with icosahedral symmetry. Canyons on the surface of the virus provide an attachment site for receptors on the surface of susceptible target cells. The attachment site for most rhinoviruses is the intercellular adhesion molecule-1 on human respiratory tract epithelium. Viral infectivity is neutralized when host immunoglobulin G binds to the surface of the virus, thereby blocking interaction between the host cell receptor and the receptor binding site located at the base of the canyon.[2]

Rhinovirus is found worldwide and causes infection throughout the year. In temperate climates, a sharp increase in the number of rhinovirus infections occurs in September after the return of children to school,[3] and the incidence of detections per person-weeks in households is related to the number of children.[4] Schoolchildren frequently transfer rhinovirus to family members; in 1 study, 73% of infections in the home could be traced by serotype to infection in a child.[5] A smaller peak of rhinovirus infections occurs in the spring.

Rhinovirus infection of humans is restricted to respiratory tract epithelium, primarily the nose and nasopharynx, and it does not appear to extend to the submucosa. The temperature of normal nasal mucosa is 33°C to 35°C, the optimal temperature for growth of rhinovirus in vitro. Rhinovirus also can infect the lower respiratory tract.[6–8] Rhinovirus RNA has been detected in blood, but rhinoviremia has not been demonstrated by culture.[9] The virus has not been detected in stool. Human rhinovirus has not been recovered from domestic animals (dogs and cats); the only animal model of infection is in primates.

Rhinovirus transmission occurs by small-particle aerosol, large-particle aerosol, or direct contact.[10] To cause infection, virus must be deposited on the nasal mucosa or conjunctiva; oral inoculation is not sufficient.[11,12] In studies of experimental[13,14] and naturally acquired[11,15] rhinovirus infections, virus often can be recovered from the hands of infected people, as well as from objects touched by infected people, including toys in a physician's waiting room.[13,15,16] Studies of young adults showed efficient transfer during brief hand contact and inoculation by finger onto conjunctival or nasal epithelium.[13] Sneezing and coughing were inefficient methods of transfer.[15] In a different experimental model, it appeared that infection could be transmitted by aerosol.[17,18] Transmission routes under natural conditions have not been established definitively, but in 1 study, interruption of hand transmission alone reduced secondary attack rates in mothers after introduction of virus by a family member.[10]

Clinical Manifestations

The symptoms of a rhinovirus cold largely are subjective; nasal congestion or discharge, sore or scratchy throat, and cough are typical complaints. In adults, physical findings can be limited to mild erythema of the nasal mucosa and pharynx. In addition, children also can have fever during the first 2 to 3 days and moderate enlargement of the anterior cervical lymph nodes. Illness generally lasts 5 to 7 days in adults, but it can persist for 10 to 14 days in children.

Both in vivo and in vitro studies have demonstrated that the respiratory tract epithelium remains intact during infection. Nasal biopsy specimens taken during and after illness showed no histologic change in the nasal mucosa other than an influx of neutrophils early in the course of infection.[19,20] Similarly, rhinovirus replication in vitro produced no apparent damage to a monolayer of nasal epithelial cells.[21]

Infection with rhinovirus begins with inoculation of the nasal mucosa. Studies using in situ hybridization techniques show that viral replication occurs in only a small number of epithelial cells at any point in time.[22,23] Infected epithelial cells initiate an inflammatory cascade by release of cytokines and chemokines, including interleukin-8 a potent chemoattractant for neutrophils. Vascular leakage allows plasma containing albumin and other serum proteins to flood the nasal mucosa. Evaluation of nasal washings has shown that viral titers and concentrations of serum albumin, neutrophils, interleukin-8, and kinins all peak approximately 48 hours after inoculation and then decline, thus paralleling the course and severity of symptoms (Fig. 238.1).[24] Localized inflammatory response limits viral replication, and symptoms improve. Between 2 and 3 weeks, sufficient neutralizing antibody is produced to block viral replication, and the infection ends.

Laboratory Findings and Diagnosis

Diagnosis can be confirmed by detection of rhinovirus in cell culture; nasal wash samples are superior to nasal swab specimens.[25,26] Optimally, 2 sensitive cell lines (WI-38 human embryonic lung fibroblasts and susceptible HeLa cells) are inoculated. Using either cell line alone misses 20% to 35% of culture-positive samples[25]; use of both cell lines increases sensitivity from 76% to 82%.[27,28] Using detection by cell culture, rhinovirus was associated with approximately 30% of symptomatic colds. Reverse transcriptase PCR (RT-PCR) technology detects rhinovirus with a sensitivity of 98% to 100%. Studies using both cell culture and RT-PCR for detection of rhinovirus from nasopharyngeal secretions of adults and children with naturally acquired colds have shown that rhinovirus is associated with 50% of all colds during year-round surveillance,[27,29] as well as 80% of colds occurring in the fall.[28] The group C rhinoviruses detected with RT-PCR have not been grown in available cell lines. The long duration of shedding of rhinoviruses can confound interpretation of a causal role in clinical settings.[4] In a prospective study in children, however, sequential detections of rhinoviruses usually represented acquisition of new strains. Moreover, febrile illnesses were significantly associated with group B rhinoviruses.[30]

Treatment

No effective treatment is available for rhinovirus colds. The capsid-binding agent pleconaril had activity,[31] and interferon α is under investigation.[32] Antihistamines, decongestants, and antitussives have not been shown to be effective in children with colds. *Echinacea* preparations are commonly believed to be effective, but a placebo-controlled, double-blind study showed no significant effect on the rate of rhinovirus infection or its symptoms.[33]

Special Considerations

Although rhinovirus infections are considered benign, self-limited infections, certain populations can experience more serious consequences. In 1 study, preterm infants with rhinovirus infection were severely compromised, and all required respiratory support.[34] In another study, rhinovirus (predominantly HRV-C) was identified in young infants admitted with a diagnosis of apparently life-threatening event.[35] Rhinovirus-associated wheezing early in life is strongly associated with recurrent wheezing and a later diagnosis of asthma. One study suggested that a subset of young children with a rhinovirus-associated first episode of wheezing, namely those with a high viral load, benefited from a 3-day course of oral prednisolone such that they experienced decreased respiratory symptoms in the short term and fewer recurrent wheezing episodes over the next 12 months.[36] Children with underlying medical conditions such as chronic pulmonary or neurologic disease also can experience more severe disease manifestations.[37,38] In symptomatic patients before hematopoietic cell transplantation, rhinovirus detection was associated with reduced 100-day survival.[39]

Prevention

Development of a vaccine is thwarted by the large number of serotypes and the serotype specificity of immunity. Transmission can be interrupted, at least in part, by the simple physical removal of virus on fingers by handwashing before inoculation of nasal or conjunctival mucosa.

Acknowledgment

Coauthor Dr. Pappas and the editors of this book acknowledge the substantial contributions of the late Dr. J. Owen Hendley to our knowledge of respiratory viruses and to this chapter. The Infectious Diseases community mourns his loss.

Pathogens and Pathogenesis

The first calicivirus was discovered in 1972 by electron microscopic examination of stool samples from children affected by an outbreak of gastroenteritis in a school in Norwalk, Ohio, several years previously.[1] This discovery of the subsequently named Norwalk virus marked the first identification of a virus as a cause of gastroenteritis. Norwalk virus and other viruses with similar morphologic features are now classified in the genus *Norovirus* of the family Caliciviridae (Fig. 239.1). Caliciviruses are small, nonenveloped, single-stranded RNA viruses that can be divided into at least 5 genera: *Norovirus, Sapovirus, Nebovirus, Lagovirus,* and *Vesivirus*.[2] Main characteristics of noroviruses and sapoviruses, also referred to as human caliciviruses, are summarized in Table 239.1. Neboviruses, lagoviruses, and vesiviruses are strictly animal pathogens and have not been detected in naturally occurring human illnesses.

TABLE 239.1

Comparison of Main Characteristics of Noroviruses and Sapoviruses

Characteristic	Noroviruses	Sapoviruses
Appearance by electron microscopy	27–35 nm virus with appearance of cup-like indentations in capsid (Fig. 239.1)	27–35 nm virus with striking cup-like depressions with hollow in middle leading to "star of David" configuration
Other names	Small round structured viruses, "Norwalk-like" viruses	"Classical" caliciviruses, "Sapporo-like" viruses
Name of prototype virus	Norwalk virus	Sapporo virus
Genogroups (G)	I–VII (GIII exclusively bovine viruses, GV exclusively murine viruses, GVI–VII exclusively canine viruses)	GI–V (GIII exclusively porcine viruses)
Immunity	Shortterm (6 mo–8 yr) homologous acquired immunity; genetic resistance or susceptibility factors	Largely unknown
Affected age groups	All ages	Mainly children
Clinical symptoms	Vomiting and diarrhea	Mild gastroenteritis with less vomiting
Asymptomatic infections	30% in volunteer studies	Common (possibly ≤75% of infections among children in

		childcare outbreaks)
Percentage of diarrheal hospitalizations among children <5 yr of age	10%–25%	<5%
Outbreak potential	High	Moderate
Modes of transmission	Fecal-oral: direct person-to-person spread; contaminated food, water or fomites; droplet spread from vomitus	Fecal-oral: person-to-person spread likely the predominant mode; occasionally contaminated food

Noroviruses are classified into 7 genogroups (G): viruses of GI, GII, and GIV cause human disease, whereas GIII, GV, GVI, and GVII contain viruses only found in animals.[3] These 7 genogroups are further subdivided into 40 genotypes,[3] among which GII.4 viruses have emerged as the leading cause of norovirus outbreaks worldwide.[4] Sapoviruses similarly are divided into 7 genogroups, 4 of which (I, II, IV, and V) contain viruses affecting humans.[5] Humans are considered the primary reservoirs for human caliciviruses, but serologic evidence of infection with bovine and canine noroviruses suggests the potential for rare zoonotic transmission.[6,7] Additionally, some evidence suggests possible infection of dogs and cats with human strains of norovirus and sapovirus.[8,9]

Noroviruses and sapoviruses infect villi of the small intestine and likely cause diarrhea by a variety of mechanisms, including both disruption of the epithelial barrier and active anion secretion.[10] Mechanisms of immunity to norovirus infection remain unclear. Immunity to 1 infecting strain does not appear to confer broad cross-protection and may be only temporary. In experimental challenge studies using high doses of Norwalk (GI.1) virus, people became susceptible to reinfection with the same strain after 6 months or less.[11,12] Modeling of community transmission based on observed disease incidence rates suggests that immunity can last 4 to 8 years.[13] High levels of antibody seem to be markers for susceptibility, rather than protection, whereas some people can be entirely refractory to infection with a particular strain.[12] This apparent paradox has been explained in part by studies demonstrating genetic factors related to susceptibility and resistance to norovirus infection. Innate resistance has been associated with mutations in the genes for the secretor enzyme, 1,2-fucosyltransferase (FUT2), leading to lack of expression of histo

–blood group antigens.[14–17] These antigens are expressed on the surface of intestinal cells and in body fluids such as saliva and serve as binding ligands for norovirus. People who express histo–blood group antigens (i.e., secretors) are susceptible to most, but not all, norovirus genotypes and typically have higher antibody levels.[14,15,17–20]

Epidemiology

Caliciviruses, specifically noroviruses, are the most common infectious causes of acute gastroenteritis in people worldwide and are second only to rotavirus among children <5 years of age.[21] In a systematic review and meta-analysis of 175 studies conducted in 48 different countries, noroviruses were detected in 18% of acute gastroenteritis cases.[21] In the United States, noroviruses are estimated to cause on average 19 million to 21 million illnesses, 56,000 to 71,000 hospitalizations, and 570 to 800 deaths annually.[22] With the implementation of universal rotavirus vaccination in the US, norovirus has surpassed rotavirus to become the leading cause of severe pediatric gastroenteritis.[23] With the introduction of rotavirus immunization in many other countries and the consequent reduction of the burden of rotavirus disease, the relative importance of noroviruses in severe pediatric gastroenteritis is similarly expected to increase in these settings.[24]

Noroviruses are highly infectious and are transmitted primarily through the fecal-oral route, either directly from person to person or indirectly by contaminated food and water (Fig. 239.2).[25] Droplet spread from vomitus also can infect people in the vicinity or can contaminate environmental surfaces, where norovirus can persist and remain infectious for several days.[26–28] These characteristics help make noroviruses the leading causes of acute gastroenteritis outbreaks in the US and Europe, responsible for approximately 50% of all reported outbreaks.[29,30] Although outbreaks occur year round, they are more common in colder months.[30,31] Periodic increases in norovirus outbreaks also have occurred in association with the emergence of new viral strains, particularly those within GII.4, resulting in seasons with increased norovirus activity.[32,33] Although the emergence of new GII.4 strains typically results in replacement of the previously predominant strain, it does not always result in an increased number of outbreaks, as observed with the most recent GII.4 New Orleans and GII.4 Sydney strains.[34,35] Fig. 239.3 shows the settings of 3243 outbreaks suspected or confirmed resulting from norovirus reported to the Centers for Disease Control and Prevention during 2009 to 2012.[36] The most common setting of reported US norovirus outbreaks is longterm care facilities, in which the predominant transmission route is direct person-to-person contact.

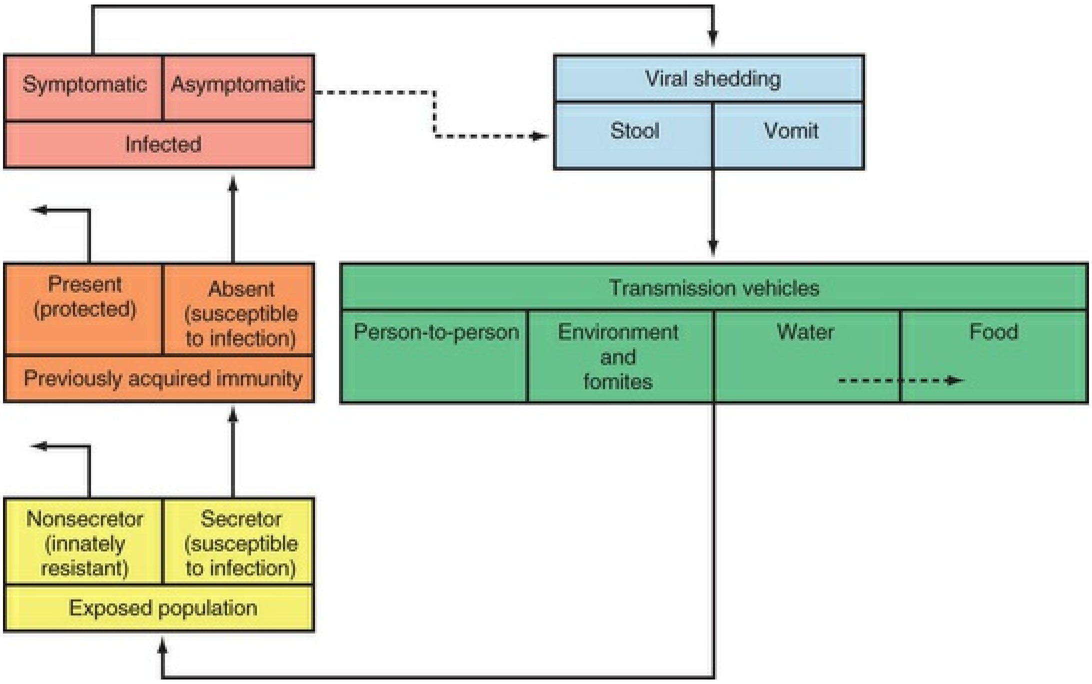

FIGURE 239.2 Transmission cycle of norovirus. Transmission is shown beginning with infected people (red box), including both symptomatic and asymptomatic infections. Virus is shed in stool and vomit of symptomatic people (blue box), as well as in the stool of asymptomatic people (dashed arrow). Subsequent transmission vehicles can include raw or ready to eat foods, drinking or recreational water, contaminated fomites or environments, and direct person-to-person contact (green box). Cross-contamination can occur among these vehicles, such as contamination of fresh produce with irrigation water or shellfish with wastewater. People exposed to contaminated vehicles include both innately susceptible and resistant people, as conferred in part by secretor status (yellow box). Among exposed people without innate resistance, some will have previously acquired immunity and therefore will be protected from infection (orange box). People without innate or acquired immunity then become infected, and the cycle begins again.

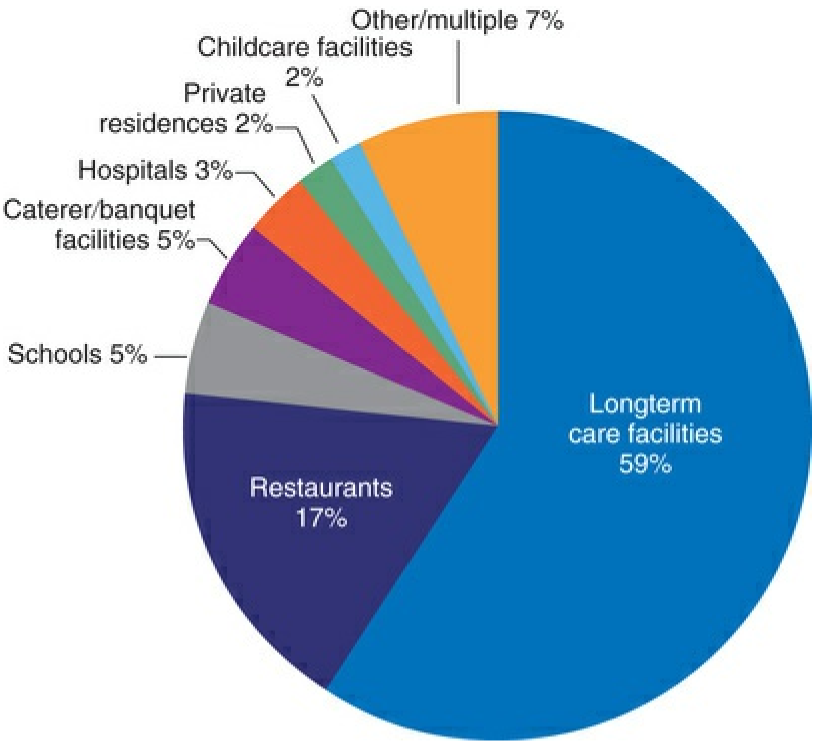

FIGURE 239.3 **Settings of 3243 outbreaks suspected or confirmed resulting from norovirus and reported to the Centers for Disease Control and Prevention through the National Outbreak Reporting System from 2009 to 2012.** (Data from Hall AJ, Wikswo ME, Pringle K, et al. Vital signs: foodborne norovirus outbreaks—United States, 2009–2012. MMWR Morb Mortal Wkly Rep 2014;63:491–495.)

Noroviruses also are the leading causes of foodborne disease outbreaks in the US. During 2009 to 2012, noroviruses accounted for 48% of all foodborne disease outbreaks with a single suspected or confirmed cause reported to the Centers for Disease Control and Prevention.[36] Outbreaks have been associated with consumption of oysters that concentrate viruses from contaminated waters, raspberries presumed to be contaminated in fields, and delicatessen meat contaminated during processing; however, outbreaks are usually linked to prepared foods (e.g., salads, sandwiches) contaminated during final preparation by an infected food worker.[36–41]

The epidemiology of sapoviruses is less well studied. A study in the US estimated 9 sapovirus cases in the community and 1 sapovirus-associated outpatient visit each year per 1000 population, representing 2% of all cases of acute gastroenteritis across the age spectrum.[42] A prospective study in the United Kingdom found similar results of 26 community cases and 2 cases in patients presenting to general practice per 1000 person-years attributable to sapovirus.[43] Although sapoviruses are a common causes of infection of infants, with seroprevalence similar to that of GII noroviruses, infections are often mild or asymptomatic.[44–46] Outbreaks of sapovirus illness are much less common than are outbreaks of norovirus, but they have been reported in schools, childcare facilities, adult longterm care facilities, and hospitals, as well as occasional foodborne outbreaks.[47–51] The broad age range of people affected in these outbreaks suggests that sapovirus infection may not be restricted to young children. Furthermore, an emergent genotype of sapovirus (GI.2) has been associated with an increased number of outbreaks in Europe that primarily affected older adults.[52]

Clinical Manifestations

Norovirus and sapovirus infections usually manifest as acute-onset vomiting with watery, nonbloody diarrhea, after an incubation period of 12 to 48 hours. Other symptoms include abdominal cramps, nausea, and occasionally low-grade fever; the term “stomach flu” is therefore commonly used to describe the illness, although the infection is not related to influenza. Although illness is generally self-limiting and full recovery can usually be expected in 1 to 4 days, symptoms can be debilitating and lead to dehydration and its sequelae requiring medical attention, especially in children <5 years of age and older adults ≥65 years of age.[18,22] Norovirus outbreaks in nursing homes also have been associated with increased rates of all-cause hospitalization and death, thus underscoring the severe impacts that norovirus infection can have in these populations.[53] Norovirus infections do not appear to result in longterm sequelae, although secondary features that have been reported include necrotizing enterocolitis in neonates, chronic diarrhea in immunosuppressed patients, postinfectious irritable bowel syndrome, and neurologic manifestations such as infantile seizures and encephalopathy.[54–58] More data are needed to confirm these observations and determine their relative frequency.

Generally, norovirus illness is less severe than is rotavirus disease, although medically attended pediatric cases of acute gastroenteritis associated with either virus have similar severity scores.[59] Clinical sapovirus infection manifests with similar but milder symptoms than does norovirus infection and with less vomiting.[46,60] Volunteer studies suggested that 30% of norovirus infections can be asymptomatic.[61] Importantly, norovirus and sapovirus can be shed in stools for 2 to 4 weeks after infection, although peak shedding occurs 2 to 5 days after infection.[50,62,63] Children and people with suppressed immune systems have been reported to shed virus for longer periods.[18] The point at which an infected person ceases to represent a significant risk of contagion is unclear.

Laboratory Findings and Diagnostic Tests

Human caliciviruses are refractory to growth in vitro, a feature that has hampered the development of diagnostic tests. In the 1990s, reverse transcriptase polymerase chain reaction (RT-PCR) became the preferred tool for diagnosing calicivirus infection; RT-PCR replaced electron microscopy and serologic tests that were insensitive, nonspecific, and generally difficult to perform.[64,65] RT-PCR platforms using TaqMan probes that allow for simultaneous detection and quantification largely have replaced conventional RT-PCR assays for laboratory diagnosis, and assays approved for use by the Food and Drug Administration are in the pipeline.[66,67] Enzyme immunoassays for norovirus antigen detection also have been developed, and at least 1 assay has been cleared for use by the Food and Drug Administration. However, because of poor sensitivity, enzyme immunoassays are not recommended for clinical diagnosis of sporadic gastroenteritis cases, although they can have utility in rapid diagnosis during outbreak investigations when multiple specimens are available.[68,69] Multipathogen molecular-based diagnostic platforms have been developed for simultaneous detection of common bacterial, parasitic, and viral causes of gastroenteritis, including noroviruses.[3]

Treatment

Treatment is supportive for dehydration and electrolyte imbalances. First-line therapy for uncomplicated viral gastroenteritis should be oral rehydration, whereas severe dehydration or shock warrants intravenous fluid therapy.[70] Antiemetics, antimotility agents, and antibiotics are not recommended.[71,72] Research and development of potential antiviral agents against noroviruses are ongoing, although no clinical trial has yet been conducted.[73,74]

Prevention

Prevention of infection should focus on standard hygienic precautions, including frequent hand hygiene, environmental disinfection, proper disposal of fecal or vomit-soiled materials, and limited contact with ill people.[75] Washing with soap and water is the preferred method of hand hygiene to prevent calicivirus transmission, with alcohol-based hand sanitizers useful only as adjuncts when hands are not visibly soiled.[76] Whenever possible, contact with ill people should be limited during the period of peak infectiousness (acute illness through 72 hours after recovery). Ill staff members in healthcare facilities and food handlers should be excluded from work until at least 48 hours after symptom resolution. Potentially contaminated environmental surfaces should be disinfected using a chlorine bleach solution with a concentration of 1000 to 5000 ppm (1 : 50–1 : 10 dilution of household bleach [5.25%]) or other approved disinfectant.[77] Current vaccine development efforts using virus-like particles have shown promise, although no vaccine against human caliciviruses has yet been licensed.[78,79]

Key Points

Epidemiology, Clinical Features, Diagnosis, and Management of Norovirus Gastroenteritis

Epidemiology

- Present throughout the world
- Affects all age groups, though greatest burden of more severe illness among young children (<5 years) and older adults (>65 years)
- Multiple modes of transmission

- Direct person-to-person contact
- Consumption of contaminated food or water
- Ingestion of airborne droplets of vomitus
- Contact with contaminated environmental surfaces

- Infectious dose: as few as 18 to 2800 virus particles
- High outbreak potential

Clinical Features

- 30% of infections can be asymptomatic
- Incubation period: 12 to 48 hours
- Disease characterized by
  - Acute-onset vomiting
  - Watery, nonbloody diarrhea
  - One or more of the following: abdominal cramps, nausea, fever, headache
- Dehydration most common complication in young patients and older adults
- Duration of illness: 12 to 60 hours

Diagnosis

- Limited availability of clinical assays for individual cases, so generally based on symptoms
- In outbreaks or for research studies, detection of norovirus by

reverse transcription polymerase chain reaction testing of stool specimens; sequencing of norovirus for genotype and cluster identification

Treatment

- Replacement of fluid and electrolytes by oral rehydration solutions or intravenous fluids
- No antiviral drug or vaccine currently available

Astroviruses

Jacqueline E. Tate

Astroviruses were first described in 1975 when they were detected by electron microscopic examination in stool specimens of infants with gastroenteritis.[1,2] Since 1990, with development of sensitive and specific diagnostic methods, including enzyme immunoassays (EIAs) and reverse transcriptase polymerase chain reaction (RT-PCR), astroviruses have been identified as relatively common causes of community-acquired and hospital-acquired gastroenteritis.[2a–2d] Astroviruses are among the most common viral causes of gastroenteritis among children after rotaviruses and noroviruses.[3]

Description of Pathogen

Astroviruses are nonenveloped, positive-sense, single-stranded RNA viruses in the family Astroviridae.[4,5] By electron microscopic examination, astroviruses are 28 to 30 nm in diameter with a smooth edge, and they sometimes have a characteristic star-like appearance in the center (Greek, *astron* meaning "star") (Fig. 240.1).[5a,5b] At least 8 distinct serotypes (HAstV 1–8) of human astrovirus are recognized, defined both antigenically and by genetic sequence differences, with several novel species described since 2008.[6–8] Serotype 1 viruses are detected most commonly, but more than 1 serotype may circulate in communities during each season.[7,9] Non–serotype 1 viruses can predominate in a season, and greater serotype diversity can be found in developing countries.[7,10–14]

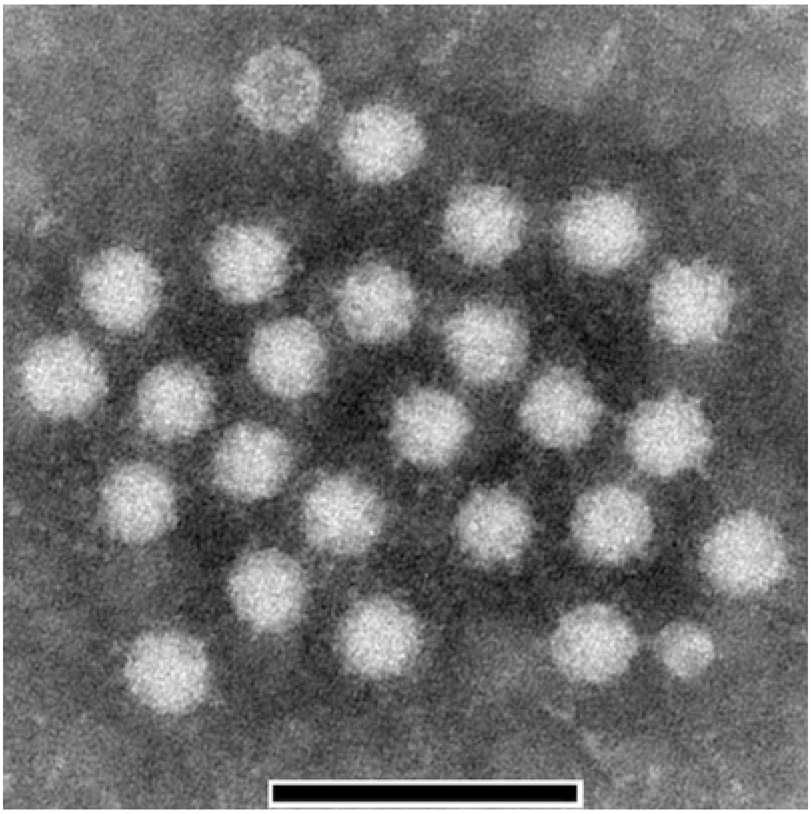

FIGURE 240.1 Astroviruses are 28 to 30 nm, have a smooth edge, and have a distinctive 5- or 6-pointed star on some particles when fecal suspension–derived virus is viewed. The smooth surface is not always present on astroviruses grown in culture and can resemble miniature versions of noroviruses. (Scale bar = 100 nm.) (Courtesy of Charles D. Humphrey, PhD, Centers for Disease Control and Prevention, Atlanta, Ga.)

Epidemiology

Like rotaviruses and caliciviruses, astroviruses have worldwide distribution and have been detected as causes of sporadic gastroenteritis and of outbreaks.[15–19] In both economically developed and developing countries, astroviruses have been detected in 2% to 9% of children treated for acute, nonbacterial diarrhea.[20] The lower proportions reported from some studies (<1%–3%) may reflect insensitive detection methods rather than true prevalence.[3,19,21–27] The mean prevalence of astroviruses globally is 11%, with detection usually higher in developing countries and in rural areas (23%) compared with urban areas (7%).[28] Since the 1990s a decreasing trend in astrovirus detection has been observed, but methodologic differences over time make such longitudinal comparisons difficult.[28]

Outbreaks of astrovirus gastroenteritis have been reported in closed settings such as schools, childcare centers, hospitals, nursing homes, and households, and they can be associated with high attack rates.[16,18,29–36] Astroviruses have been reported to be responsible for 5% to 16% of cases of nosocomial gastroenteritis in children's hospitals.[32,37,38]

Although astroviruses have been detected in all age groups, most infections occur in children <2 years of age.[15,16,23,39] Most adults have serum antibodies against astroviruses that are acquired early in life.[40] Disease in adults is uncommon. In volunteer studies, most adults challenged with virus did not become infected or develop diarrhea.[41] However, illness among teachers during school outbreaks has been described, perhaps as a result of a large dose of virus in this type of setting or a different mechanism of spread.[29,30] Outbreaks among older adults may reflect waning immunity associated with increasing age.[33–35] Astroviruses also have been associated with disease in immunocompromised adults.[42] Astroviruses have been found in stool from asymptomatic people. Further studies are needed to define the role of these viruses as pathogens more clearly.

Transmission is by the fecal-oral route, generally through person-to-person contact, but transmission occasionally can occur by contaminated food, water, or fomites.[29,30,43,44] The infectious dose has not been established. In temperate climates, astrovirus shows a seasonal distribution similar to that of rotavirus with a peak in winter; seasonality is less clear in tropical settings but tends to peak during the rainy season.[12,19,21,22,39,45,46]

Clinical Manifestations

The mean incubation period for astrovirus infections is 4.5 days.[47] Symptomatic illness occurs more commonly and with increased symptoms in infants and young children, although asymptomatic infections can occur at all ages.[17,18] Clinical symptoms generally are milder but similar to symptoms caused by rotavirus, with 2 to 5 days of watery diarrhea, often accompanied by vomiting and less often by high fever and abdominal pain.[23,32,39,48] Illness generally is mild and self-limited, but malabsorption and lactose intolerance have been reported following infection.[23,39,49] In highly immunocompromised children, astroviruses can spread systemically and cause severe, disseminated, lethal infections.[50] Stools do not contain blood or mucus. Children can shed virus 1 to 2 days before illness and for a median of 5 days after the onset of symptoms.[18,31,32] Prolonged diarrhea has been reported among children with malnutrition and in immunocompromised patients. Asymptomatic viral excretion among healthy children has been reported for 3 weeks when more sensitive detection methods have been used.[18] Persistent excretion occurs in immunocompromised patients.[51] Because illness is largely confined to young children and older adults, infection probably confers protection that is relatively durable. Astroviruses have been identified as potential, but uncommon, risk factors for intussusception in young children in several studies.[52–54]

Laboratory Findings and Diagnosis

Since 1990, many improvements have been made in diagnostic methods for astroviruses, including adaptation to grow in continuous cell lines, sequencing and elucidation of the structure of the genome, and development of improved methods of detection, including EIAs and RT-PCR.[3] Commercial EIAs to detect viral antigen in stool are available in many countries and offer sensitive and specific methods to diagnose infections; none of these EIAs are available in the United States.[2b,2d,3] Commercial monoplex and multiplex real-time RT-PCR kits are available. Other diagnostic methods include serum EIA for astrovirus antibodies and electron microscopic examination; these methods are used primarily in research settings.[3] Next-generation technologies (e.g., such as whole-genome sequencing and viral metagenomics) are becoming available and can help improve understanding of the basis of viral pathogenesis and identify emerging strains.

Treatment

The mainstays of management are rapid assessment, correction of fluid loss and electrolyte disturbances, and maintenance of adequate hydration. Oral rehydration therapy with appropriate glucose and electrolyte solutions is sufficient for most patients. Intravenous rehydration is required for children severe dehydration, shock, or intractable vomiting. Children should maintain caloric intake as best as possible, with maintenance of diet.[55] Breastfed infants should continue to nurse on demand, and formula-fed infants should continue formula immediately on rehydration. Children receiving semisolid or solid foods should continue to receive their usual diet during episodes of diarrhea, although substantial amounts of foods high in simple sugars (carbonated soft drinks, juice, gelatin desserts) should be avoided because the osmotic load could worsen diarrhea. No specific antiviral therapy exists.

Prevention

No vaccine is available, and none is in clinical trial. Prevention of astrovirus infections is best accomplished through good hygiene, including attention to appropriate hand hygiene practices.

Key Points

Astroviruses

Epidemiology

- Worldwide distribution.
- Causes of sporadic gastroenteritis and outbreaks
- Detected in all age groups, but most infections occur in children <2 years of age
- Transmission by the fecal-oral route, generally through person-to-person contact, but transmission occasionally can occur by contaminated food, water, or fomites

Clinical Manifestations

- Mean incubation period is 4.5 days.

- Symptomatic illness is more common, and symptoms are exaggerated in infants and young children.

- Clinical symptoms generally are mild and self-limiting.

- 2 to 5 days of watery diarrhea, often accompanied by vomiting and less often by high fever and abdominal pain

- Children can shed virus 1 to 2 days before illness and for a median of 5 days after onset of symptoms.

- Persistent excretion occurs in immunocompromised patients

Diagnosis

- Commercial enzyme immunoassays detect viral antigen in stool.

- Sensitive and specific method to diagnose infections

- None available in the United States

- Commercial monoplex and multiplex real-time reverse transcriptase polymerase chain reaction kits are available.

Management

- No specific therapies available

- Mainstays of management

- Rapid assessment

- Correction of fluid loss and electrolyte disturbances

- Maintenance of adequate hydration

Prevention

- Good hygiene
- Attention to appropriate hand hygiene practices

Hepatitis E Virus

Eyasu H. Teshale

Hepatitis E virus (HEV), the major etiologic agent of enterically transmitted non-A hepatitis worldwide, is a spherical, nonenveloped, single-stranded, positive-sense RNA virus that is approximately 32 to 34 nm in diameter.[1] HEV is the sole member of the family Hepeviridae, genus *Hepevirus*.[2] The HEV genome, which is approximately 7.2 kilobases, consists of 3 open reading frames (ORF 1, ORF 2, and ORF3). HEV is classified into 4 major genotypes, which represent a single serotype.[3] Genotype 1 includes Asian and African strains; genotype 2 includes Mexican and some African strains. Both genotypes 1 and 2 are associated with large epidemics. Genotype 3 includes strains from sporadic human cases from industrialized countries including the United States, Japan, and countries in Europe, as well as animal strains from swine. Genotype 4 includes strains from human cases in Asia (mainly Taiwan and China) and animal strains from swine.

Following HEV infection, both immunoglobulin (Ig) M and IgG antibodies to HEV (anti-HEV) are elicited (Fig. 241.1). IgM anti-HEV generally is detectable at the time of symptom onset or liver enzyme elevations; levels decline during early convalescence.[4] IgG anti-HEV persists and appears to provide protection against disease,[5] but the duration of immunity after infection has not been determined. One study demonstrated persistence of IgG anti-HEV in approximately 50% of people studied at least 14 years after infection.[6]

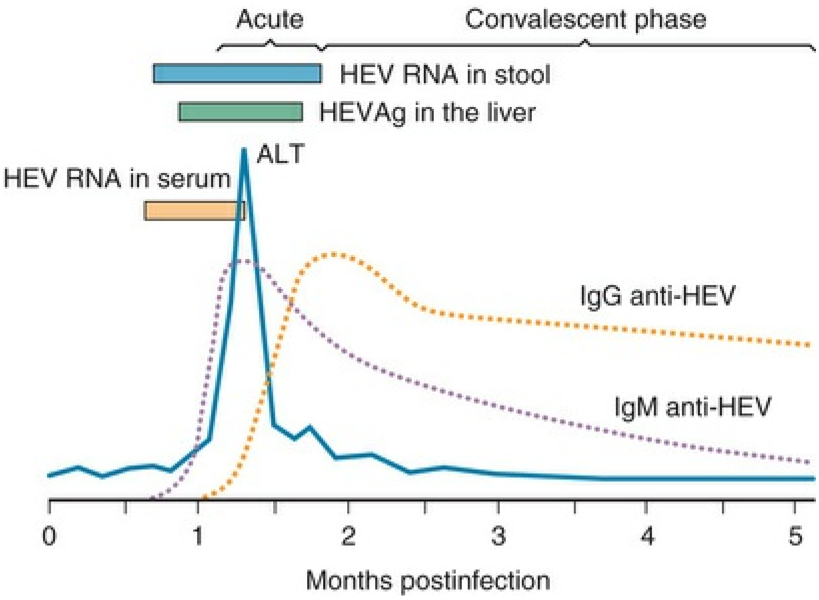

FIGURE 241.1 **Typical serologic and biochemical response to hepatitis E virus infection. ALT, alanine aminotransferase; anti-HEV, antibodies to hepatitis E virus; HEV, hepatitis E virus; HEVAg, hepatitis E virus antigen; Ig, immunoglobulin;** (Courtesy of Dr. K. Krawczynski.)

Histopathologic features of HEV infection include both classic acute viral hepatitis, with focal hepatocellular necrosis, ballooned hepatocytes, and acidophilic degeneration of hepatocytes, and cholestatic hepatitis, with bile stasis in canaliculi and gland-like transformation of hepatocytes.[7,8]

Epidemiology

HEV infection manifests in 2 distinct clinicoepidemiologic patterns mainly related to viral genotype.[9] In hepatitis E epidemics, HEV (genotype 1 or 2) is transmitted primarily by the fecal-oral route. Fecally contaminated drinking water is the most commonly documented vehicle of transmission, and outbreaks usually occur during the rainy season and sometimes affect thousands of people.[5,7,10] HEV infection also accounts for most cases of acute sporadic hepatitis in both children and adults in endemic countries.[11–13] Risk factors for sporadic hepatitis E have not been well defined.

Many of the hepatitis E cases in the US and Western Europe have been reported among travelers returning from HEV genotype 1–endemic areas.[14–16] Although outbreaks of hepatitis E do not commonly occur in the US and Western Europe, increasing numbers of autochthonous cases unrelated to travel are being reported.[17,18] The HEV strains isolated from patients with autochthonous hepatitis E belong to HEV genotype 3 and 4 and have close genetic resemblance to the swine HEV strains isolated from local farms, a finding suggesting that swine could serve as zoonotic source for human disease. However, the mechanism of transmission from swine to humans in these autochthonous cases is unknown. The worldwide distribution of hepatitis E has not been determined fully, in part because of a lack of well-standardized serodiagnostic tests and a lack of surveillance for hepatitis E.[19,20] However, HEV appears to be endemic globally, given the high seroprevalence of anti-HEV in different populations, the high seroprevalence in animals, the frequent occurrence of outbreaks, and the finding that a significant proportion of sporadic acute viral hepatitis is caused by HEV.[21–24] Large outbreaks of HEV have been documented over a wide geographic area, primarily in developing countries with inadequate environmental sanitation (Fig. 241.2).[10,25–30]

Identification of IgG anti-HEV in animal species in many regions of the world provides credence to the speculation that HEV is a zoonotic agent.[31,32] HEV can be transmitted by food, as evidenced by disease following consumption of uncooked offal meat from wild boar and sika deer in Germany and Japan and after consumption of raw figatellu, a traditional pig liver sausage in France.[33–35] Vertical transmission of HEV from infected mother to fetus is common.[36] In epidemic settings, person-to-person transmission can contribute to significant transmissions.[37] Nosocomial transmission, presumably by person-to-person contact and by transmission through blood transfusion, has been reported.[38,39]

Clinical Manifestations

Infection can be asymptomatic, it can be clinically inapparent, or can result in clinically evident disease. The incubation period ranges from 15 to 60 days (mean, 40 days). Typical acute clinical signs and symptoms are indistinguishable from those of other types of viral hepatitis and consist of jaundice, malaise, anorexia, nausea, vomiting, abdominal pain, dark urine, fever, and hepatomegaly.[10,12,13,40,41] Other less common signs and symptoms are diarrhea, arthralgia, pruritus, and urticarial rash. The period of infectivity after acute infection has not been determined, but virus excretion in stool has been demonstrated beginning approximately 2 weeks before elevation of serum hepatic enzyme levels and ending by the time liver enzyme levels return to normal.[42,43] In most outbreaks, the highest rates of clinically evident disease have occurred in young to middle-aged adults; lower disease rates in younger age groups could be the result of anicteric or subclinical infections.[5,19,25,28] In contrast, most autochthonous HEV infection occurs among older men (usually >40 years of age).[44] No evidence of chronic HEV infection has been detected in longterm follow-up of otherwise healthy people.[45] However, chronic HEV infection occurs among adult recipients of solid organ transplants, people with acquired immunodeficiency syndrome, and people with hematologic malignant diseases.[46–48] Association of autochthonous HEV infection with neurologic signs and symptoms including Guillain-Barré syndrome is recognized increasingly, as is cirrhosis in immunosuppressed populations.[49,50] Cases of chronic HEV infection that rapidly progressed to cirrhosis have been reported among children who received bone marrow transplants for hematologic malignant diseases and among liver transplant recepients.[51,52] HEV also causes severe hepatic decompensation in patients with preexisting chronic liver disease.[53,54]

The mortality rate observed during epidemics of HEV infection is approximately 0.1% to 4%.[55] However, fulminant hepatitis occurs more frequently among pregnant women, particularly in the third trimester, and case-fatality rates can reach 25%.[56–58] Mortality rates in young children can be high.[55,59] The reason for the high mortality rates among pregnant women is unknown; causes of death include hepatic encephalopathy and disseminated intravascular coagulation.[60,61] In a prospective study of 26 pregnant women with HEV infection, 15 patients had fulminant hepatic failure and 11 patients had nonfulminant disease. Five mothers died undelivered, 2 aborted, 4 had premature delivery, and 15 delivered full-term infants. Fifteen (79%) of the 19 live born infants had evidence of HEV infection at birth (12 had IgM anti-HEV and 10 had HEV RNA detected). Neonates had icteric hepatitis (7), anicteric hepatitis (5), and jaundice with normal hepatic enzymes (3). In the first week of life 7 infants died, 1 of prematurity and 6 of HEV infection; 5 of 6 mothers of infants who died had fulminant hepatic failure. Vertical transmission of HEV to the fetus with poor perinatal outcome has occurred in 30% to 100% of mothers with HEV infection.[62]

Laboratory Findings and Diagnosis

Laboratory findings are similar to those of other types of viral hepatitis and include elevated serum levels of bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and γ-glutamyltransferase.[8,9,41] Resolution of hyperbilirubinemia and serum aminotransferase elevations generally occurs within 1 to 6 weeks after onset of illness.

Enzyme immunoassays to detect IgM and IgG anti-HEV in serum are available commercially, but none is cleared for clinical use in the US by the Food and Drug Administration. The sensitivity and specificity of these tests vary significantly.[20] Reverse transcriptase polymerase chain reaction can be used to detect HEV RNA in serum and stool but is not available routinely in diagnostic laboratories. Other tests initially used to detect HEV infection are the immunohistochemistry test to identify HEV antigen in liver tissue and the fluorescent antibody-blocking assay to identify the anti-HEV reaction to HEV antigen in serum. However, both these assays have limited sensitivity and are available only in a few research laboratories. Western blot assays can detect IgM and IgG anti-HEV in serum but are less sensitive. Interpretation of test results can be difficult, and in low-endemic regions a definitive diagnosis generally requires use of multiple tests, consideration of risk factors, and exclusion of other causes of acute hepatitis (Table 241.1).

TABLE 241.1

Interpretation of Hepatitis E Test Results in Patients With Clinical Hepatitis

		Result	
Specimen	**Assay**	**Positive**	**Negative**
Serum	IgM anti-HEV	Consistent with current or recent HEV infection; in most cases, IgG anti-HEV also detected	Consider other causes of hepatitis; if acute hepatitis E suspected, test for IgG anti-HEV, HEV RNA
	IgG anti-HEV	Consistent with past or current HEV infection; test for IgM anti-HEV or HEV RNA to confirm current or recent infection	If acute hepatitis E suspected, test for IgM anti-HEV or HEV RNA
Serum or stool	HEV RNA	Current infection	Cannot exclude current infection

anti-HEV, antibodies to hepatitis E virus; HEV, hepatitis E virus; Ig, immunoglobulin.

Treatment

Treatment is supportive. Data are not available to evaluate the efficacy of antiviral agents or other specific therapies. In solid organ transplant recipients with chronic hepatitis E, discontinuation of immune suppressor drugs is associated with sustained virologic response.[63] In some instances, pegylated interferon and ribavirin were used successfully to treat chronic HEV infection.[64,65]

Prevention

Prevention relies primarily on providing clean drinking water and avoiding contamination of drinking water stored in home. Prudent hygienic practices when traveling to developing countries consist of avoiding drinking water (and beverages with ice) of unknown purity and eating uncooked fruits and vegetables that are not peeled and prepared by the traveler.

Studies conducted during outbreaks have demonstrated that anti-HEV from previous exposure protects against clinical disease.[5] Passive immunoprophylaxis with convalescent serum in nonhuman primates has been shown to prevent disease but not infection.[66] However, immune globulin prepared from plasma collected in low-endemic areas is not effective in preventing clinical disease in humans.[39] The efficacy of immune globulin prepared from plasma collected in high-endemic areas is unclear.[39,67,68] In studies of prototype recombinant vaccines, animals were protected against disease but not against infection, as indicated by detectable viremia and viral excretion.[69,70] In a large phase III trial, a recombinant protein vaccine (truncated ORF-2 protein) was found to be safe and effective in preventing hepatitis E.[71] This vaccine is now approved for use in China but is not widely available. This vaccine could be a powerful new tool for prevention of hepatitis E and may have a role in preventing outbreaks in regions and settings where outbreaks commonly occur.[72]

Newly Identified Viruses

Patients with acute hepatitis in whom recognized viral and nonviral causes have been excluded are considered to have non–A through E (non–A-E) hepatitis.[73] Since 2000, new viruses, which include GB virus (GBV) agents (previously known as hepatitis G virus),[74] transfusion transmitted virus, and Sendai virus, have been identified as possible causes of non–A-E hepatitis.[75–77] However, their role in the origin of non–A-E hepatitis has not been established, and their pathogenic role is not clear. Studies have shown that GBV does not replicate in the liver of people coinfected with hepatitis C virus and GBV, a finding suggesting that GBV is not a hepatotropic virus.[78,79] Although a viral origin of non–A-E hepatitis possibly exists, efforts to find the potential etiologic agent have not yet succeeded.

Classification of Fungi

Thomas F. Patterson, Deanna A. Sutton

Fungal disease contributes significantly to patients' morbidity and mortality in certain clinical settings. Extensive medical interventions, immunosuppression, and a heightened awareness of fungal disease, particularly opportunistic mycoses in the setting of immune compromise, have all necessitated an increased understanding of fungal etiologic agents and their classification, identification, and clinical manifestations.

The Agents

Definition.

Fungi are heterotrophic (lacking chlorophyll) eukaryotic organisms surrounded by a rigid cell wall composed mostly of chitin, glucan, chitosan, mannan, and glycoproteins. They have a nucleus surrounded by a membrane, and their replication is by both mitosis (asexual) and meiosis (sexual). Fungi range from simple, single-celled organisms, mostly yeasts, to complex filamentous mold species and basidiocarps (mushrooms).[1] Yeasts typically are round to oval with budding cells (blastoconidia). Yeasts mostly are small, white to cream-colored colonies on Sabouraud dextrose agar, although some species can be pink to salmon colored. The term *black yeast* is applied loosely to the yeast form of the mold genus

Exophiala and other closely related genera. Molds are multicellular, produce an extensive mycelium (filamentous), are variously colored, and have several modes of reproduction that may be asexual (conidiogenesis yielding conidia), sexual (sporogenesis yielding spores), or both. The classic primary mold pathogens such as *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis,* and *Paracoccidioides brasiliensis* are thermally dimorphic in that they can exhibit both a yeast stage (spherules for *Coccidioides* spp.) and a filamentous phase, depending on their growth in the host or under laboratory conditions. Other molds can be referred to as pleomorphic (i.e., can demonstrate multiple morphologic forms under laboratory conditions). This pleomorphism is discussed further when considering appropriate naming of molds (taxonomy and nomenclature).

Classification.

The Kingdom Fungi is arranged in a hierarchical classification system with each rank denoted by a particular ending: phylum, -mycota; subphylum, -mycotina; class, -mycetes; order, -ales; family, -aceae. Most of the clinically significant genera in the kingdom Fungi are within the phyla Ascomycota, Basidiomycota, subphylum Mucoromycotina, and subphylum Entomophthoromycotina.[2] Herein are contained members of the order Mucorales, which includes most genera inciting mucormycosis, as well as the Entomophthorales, inciting entomophthoramycosis. An example of an abbreviated classification for the fungus *Microascus cirrosus* would be as follows: kingdom Fungi, subkingdom Dikarya, phylum Ascomycota, order Microascales, family Microascacaea, genus *Microascus*, species *Microascus cirrosus*. Closely related parafungal organisms in the genera *Pythium* and *Lagenidium* are in the kingdom Streminipila (Stramenopila), phylum oomycota, whereas *Rhinosporidium* is in the supergroup Opisthokonta, division Holozoa.[3]

Taxonomy and Nomenclature.

Taxonomy refers to the classification of fungi in a very systematic way, and nomenclature refers to the assigning of names. These tasks now are under the auspices of the International Code of Nomenclature for algae, fungi, and plants. The Melbourne Code, implemented on January 1, 2013, introduced sweeping changes into the naming of fungi and resulted in the elimination of multiple names for the same organism that produces various morphologic forms (dimorphism or pleomorphism).[4] Thus, for example, the use of both the teleomorph (sexual) name *Pseudallescheria boydii* and its anamorph name *Scedosporium boydii* (previously thought to be *Scedosporium apiospermum*) no longer is permitted.[5] Going forward, the accepted name is *Scedosporium,* and similar changes are noted for various genera. The preferred name is no longer the teleomorph state, as was previously designated, but the oldest validly published name, which may be either the anamorph or teleomorph.

Laboratory Findings and Diagnosis

Collection and Examination of Specimens

The 2012 publication by the Clinical and Laboratory Standards Institute entitled *Principles and Procedures for Detection of Fungi in Clinical Specimens—Direct Examination and Culture: Approved Guideline,* is an excellent source for ensuring that the specimen being examined or cultured is appropriate for the etiologic agent being sought.[6] Consultation with the laboratory before specimen collection, however, is always recommended when the clinical history suggests potentially uncommon, unusual, or atypical organisms. Specimen types, rejection criteria, and specimen processing are well defined in this document, including blood culture for fungal organisms. Although the use of homogenization or grinding of specimens often facilitates the recovery of *Histoplasma capsulatum,* this method should never be used for member of Mucorales and for most other filamentous fungi because it is deleterious to fragile fungal hyphae. Direct examination of specimens with various stains such as the Gram stain, 10% potassium hydroxide preparations, calcofluor white fluorescent stain, India ink, and others is always recommended. Histopathologic stains such as hematoxylin and eosin and Gomori methenamine silver stain should be routine for tissue specimens, and additional special stains should be added when indicated (e.g., Fontana-Masson stain for melanin, mucicarmine for *Cryptococcus*). A comprehensive review of the histopathologic diagnosis of fungal infections is available.[7]

Culture and Identification

Phenotypic Identification.

The recovery of etiologic agents, both yeasts and molds, requires the appropriate media, incubation temperatures, and length of incubation. Several resources are available defining these parameters, including a document published by the Clinical and Laboratory Standards Institute.[6] Several systems are available for yeast recovery and identification, both manual and automated, and these systems often are determined by the laboratory's size and the population of patients served. Mold recovery and identification can be more problematic, so a few salient comments are included here regarding their identification. Although Sabouraud dextrose agar may be useful in recovery, the morphologic features of many molds are atypical on this medium, and a plant-based medium such as potato dextrose agar always should be incorporated into the battery of mold recovery and identification media. Other plant-based media and extended periods of incubation also may be required for the development of diagnostics structures for some opportunistic mold pathogens.

Molecular Identification.

Many larger or reference facilities have begun to incorporate molecular identification of both yeast and molds, either on a routine basis or for individual isolates. The method most commonly used is Sanger sequencing with identification by comparative sequence analysis.[8] This method compares sequence data for the isolate in question against a database of organisms to determine the percentage of similarity to known, credible deposits in the database, preferably compared with type strains. Identification by molecular sequencing always should be compatible with phenotypic identification.

Protein Analysis.

An additional tool for fungal identification is matrix-assisted laser desorption/ionization–time of flight mass spectrometry. This technique has not been used extensively because of the cost of the equipment, the need for more effective protein extraction methods for some genera, and less than robust databases, particularly for molds. These limitations are being overcome, however; yeast identification is becoming more common, and mold databases are being improved significantly.[9]

Clinical Manifestations

Both the functional integrity of the host's immune system and an intact skin barrier are major determinants of disease expression. Table 242.1 contains specific risk factors. The spectrum and severity of infections, as well as the pathologic entities, often overlap, however (see Table 242.2). For example, invasive candidiasis and cryptococcosis are frequent infections in immunocompromised hosts. However, superficial candidal infections occur in healthy infants, and cryptococcal infections can occur in otherwise healthy people. Similarly, various hyaline and phaeoid molds, as well as member of Mucorales, can cause clinical and pathologic entities that may be indistinguishable, and clinical entities that normally are superficial subsequently can become invasive. Thus, with the foregoing limitations and the difficulty of precise placement taken into account, the manifestations of fungal disease can be divided broadly into 3 main categories: primary systemic infections, opportunistic infections, and superficial/inoculation mycoses (see Table 242.2). This simple categorization also does not take into account community versus healthcare acquisition or the sometimes broad, overarching clinical presentations of an increasingly diverse number of fungal infections. The concept, however, is useful.

Primary Systemic Mycosis.

The primary systemic mycoses (histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis) are caused by the thermally dimorphic, endemic pathogens *Histoplasma capsulatum, Blastomyces dermatitidis or Blastomyces gilchristii, Coccidioides immitis or Coccidioides posadasii* and *Paracoccidioides brasiliensis or Paracoccidioides lutzii*. These agents are capable of causing disease in immunologically competent hosts. Sometimes also included are the genera *Emmonsia* and *Sporothrix*, the agents of adiaspiromycosis and sporotrichosis.[10]

Opportunistic Mycoses.

Opportunistic mycoses are caused by less virulent agents, and invasive disease with these agents almost always occurs in immunocompromised people or those with indwelling foreign bodies. Many such infections are nosocomial. Examples include invasive candidiasis, aspergillosis, cryptococcosis, and mucormycosis.

Superficial or Inoculation Mycoses.

These infections may be superficial or subcutaneous, and they can result from skin contamination or inoculation through compromised integumentary barriers. An example of superficial infection is dermatophytosis. Examples of subcutaneous infection include mycetoma and the cutaneous manifestations of mucormycosis. Mycetoma, a chronic, destructive localized infection of skin, soft tissue, fascia, and bone, can be caused by a variety of true fungi (eumycotic mycetoma), as well as by several aerobic actinomycetes (actinomycotic mycetoma).

Key Points

Overview of Fungi and Fungal Infections

Microbiology

- Agents of hyalohyphomycosis: molds that are hyaline in tissue; variously colored or lightly pigmented in culture and associated with soil, water, and decomposing vegetation. Species include *Aspergillus* spp. and other genera including *Fusarium,* the *Pseudallescheria boydii* species complex, *Paecilomyces, Chrysosporium, Penicillium,* and others.

- Agents of phaeohyphomycosis: melanized or dematiaceous (darkly pigmented) molds or yeast-like fungi associated with soil, water, decomposing vegetation. More than 150 species and 70 genera, including *Bipolaris, Alternaria, Scedosporium prolificans, Exophiala, Exserohilum, Cladosporium, Curvularia, Cladophialophora, Scopulariopsis,* and others

- Many fungi now referred to as a species complex because of phylogenetic, phenotypic, and physiologic differences in strains

Epidemiology

- Infections occur worldwide, most commonly in severely immunocompromised children, usually following inhalation of conidia.

- Infections can follow direct inoculation from trauma or localized infection (keratitis, sinusitis, otitis).

- Specific exposures are associated with some organisms (water aerosols for *Fusarium;* or near-drowning for *Pseudallescheria boydii* species complex; outbreaks caused by contaminated solutions, e.g., *Fusarium* keratitis).

Clinical Features

- Cutaneous infection: follows trauma in immunocompetent or compromised children; slowly increasing nodular or ulcerative lesions; also can reflect disseminated infection (fusariosis)

- Pulmonary infection: follows inhalation; symptoms including productive cough, fever, weight loss, shortness of breath, hemoptysis; nonspecific radiographic infiltrates

- Disseminated infection: severely immunocompromised children; neurotropism with brain abscess common for some organisms (agents of phaeohyphomycosis such as *Cladophialophora bantiana*)

Diagnosis

- Recovery of organism in culture from specimens of body fluids or tissue

- Microscopic examination of pathologic material: nonspecific histopathologic features for agents of hyalohyphomycosis; beaded irregular appearance of pigmented hyphae for agents of phaeohyphomycosis

- Melanin staining by Masson-Fontana method useful for agents of phaeohyphomycosis

Treatment

- Traditionally amphotericin B (or lipid formulation), but many species resistant to polyenes

- Activity and clinical use of voriconazole or posaconazole reported in case series; itraconazole limited to less seriously ill

Candida Species

P. Brian Smith, William J. Steinbach

Advances in medical therapy have allowed for the improved survival of increasingly immunocompromised and critically ill patients. These improvements have augmented the frequency as well as the morbidity and mortality associated with *Candida* infection in infants and children.

Epidemiology

Although more than 200 identified species of *Candida* have been identified, only approximately a dozen appear to cause disease in children, including *C. albicans, C. parapsilosis, C. tropicalis, C. glabrata, C. krusei, C. lusitaniae, C. stellatoidea, C. kefyr, C. pseudotropicalis, C. dubliniensis, C. intermedia,* and *C. guilliermondii.*[1–4]

C. albicans is the most commonly isolated species in children.[1,5,6] In a prospective study of neonatal candidiasis, *C. albicans* was isolated as the causative organism in 66% (38 of 58) of cases.[1] Similarly, *C. albicans* was isolated in 54% (31 of 57) of pediatric patients in the first year following hematopoietic stem cell transplantation.[7] However, the epidemiology of invasive candidiasis is changing, and the percentage of cases caused by *C. albicans* has declined from more than 80% to as low as 29% in some centers.[5,8] Despite these trends, *C. albicans* continues to be associated with increased rates of end-organ damage and a higher attributable mortality rate relative to other *Candida* species.[9,10]

C. parapsilosis is of particular importance as a cause of invasive candidiasis in neonatal and pediatric patients.[1,11] In a cohort of infants of <1000 g birth weight who had invasive *Candida* infections, 43% (132 of 307) of cases were caused by *C. parapsilosis*.[10] *C. parapsilosis* also is the most common species found colonizing the hands of healthcare personnel,[12] a finding suggesting a possible vehicle of transmission. In animal models of infection, *C. parapsilosis* is less virulent than other *Candida* species and is associated with lower mortality rates.[1,10,13] *C. parapsilosis* is important to distinguish from other species because of its occasional lower susceptibility to the echinocandin antifungal agents.

C. glabrata and *C. krusei* are less commonly isolated species but are important because they often are resistant to fluconazole.[14] In adults, in whom the use of fluconazole for prophylaxis is more widespread, *C. glabrata* is increasing in incidence and is the second or third most common cause of candidiasis.[15,16] *C. tropicalis* is considered to be the second most virulent species behind *C. albicans* and has increasingly been isolated.[8] *C. lusitaniae,* which is resistant to amphotericin B formulations, is less frequently isolated but is important given its unique resistance pattern. *C. dubliniensis*, once thought to be an "atypical" *C. albicans*, is a separate species often found in human immunodeficiency (HIV)–infected patients.[17] *C. guilliermondii* has been reported as a cause of bloodstream infections (BSIs) in patients with cancer, and *C. kefyr* is a reported cause of esophagitis.[18,19]

Candida species are the third most common pathogens in nosocomial BSIs among premature infants.[20–22] A prospective study of 2847 infants admitted to 6 neonatal intensive care units (NICUs) revealed a cumulative incidence of 0.3% (3 of 1139) in infants weighing more than 2500 g, 3% among very low birth weight (VLBW; <1500 g birth weight) infants, and 7% among extremely low birth weight (ELBW; <1000 g birth weight) infants.[10,23] The mean age at diagnosis was 15 to 33 days of life.[6,24] However, the incidence of invasive candidiasis among premature infants has declined since the 1990s.[25–27] Among infants discharged from 322 NICUs, the incidence of invasive candidiasis decreased from 3.6 episodes per 1000 infants in 1997 to 1.4 episodes per 1000 infants in 2010.[27]

The mortality rate from all *Candida* species in premature infants has been reported consistently at 20% from large multicenter studies.[10,13,21,22] In addition to a high mortality rate, invasive candidiasis in infants is associated with significant morbidities in survivors, including poor neurodevelopmental outcome, periventricular leukomalacia, chronic lung disease, and severe retinopathy of prematurity.[28–31]

Candida also is isolated commonly in hospitalized older pediatric patients. In an examination of more than 3400 BSIs in patients 16 years of age or younger, *Candida* was the third most commonly isolated organism.[32] A study of more than 500 patients in 35 pediatric ICUs (PICUs) revealed *Candida* to be the second most common cause of nosocomial infections.[33] Mortality rates also are substantial in pediatric patients. Candidemia was associated with a mortality rate of 16% in 1108 pediatric cases diagnosed outside the neonatal period,[34] and the mortality rate in another cohort of 64 PICU patients with candidemia cases (70% of which were caused by non-*albicans* species) was 28%.[35]

Clinical Manifestations

Superficial and Mucosal Infections

Oropharyngeal Candidiasis (Thrush).

Thrush, commonly found in infants and immunocompromised children, is characterized by pearly, white, curd-like, material visible on the buccal and gingival mucosa.[36] The underlying mucosa can appear erythematous or normal in color. Often painful, thrush can lead to inadequate nutritional intake and subsequent dehydration. Thrush occasionally progresses to esophagitis, laryngitis (Fig. 243.1), or invasive disease in severely immunocompromised patients. Newborn infants often are colonized from the mother's genital tract. In hospitalized neonates, the median age of onset is 9 to 10 days. Consistently, *C. albicans* is the species most commonly isolated.[37]

Diaper Dermatitis.

Candida diaper dermatitis is characterized by a confluent erythematous rash with satellite pustules.[38] Among term infants, diaper dermatitis is most common from 7 to 9 months of age, but it manifests earlier in premature infants. Diaper dermatitis in term infants is rarely associated with systemic disease. However, in a prospective study of VLBW infants, 32% of infants with mucocutaneous involvement (largely diaper dermatitis) developed invasive candidiasis.[39]

Esophagitis.

Candida esophagitis occurs most often in severely immunocompromised people such as HIV-infected patients. Esophagitis can occur in the absence of thrush.[40] Patients commonly present with dysphagia or odynophagia. Definitive diagnosis requires endoscopy for biopsy, but often the diagnosis can be made by clinical presentation or observation of mucosal irregularities on barium esophagram. In immunocompromised patients, including people with acquired immunodeficiency syndrome (AIDS), *Candida* esophagitis can occur simultaneously with cytomegalovirus and herpes simplex infection or reactivation.

Chronic Mucocutaneous Candidiasis.

Persistent or recurrent *Candida* infections of the skin, mucous membranes, and nails is termed *chronic mucocutaneous candidiasis*.[41] Affected patients have heterogeneous defects in T-lymphocyte–mediated immunity and poor proliferative responses specifically to *Candida* species. Although often phenotypically similar, the diverse group of underlying disorders and conditions predisposing patients to chronic mucocutaneous candidiasis includes HIV, inhaled corticosteroid use, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, and Job syndrome.[42,43]

Vulvovaginitis.

Although vulvovaginitis occurs in 75% of healthy women over the course of their lifetimes, certain conditions are associated with increased risk, including HIV infection, pregnancy, diabetes mellitus, and exposure to broad-spectrum antibiotic agents.[44] More than 80% of cases of vulvovaginitis are caused by *C. albicans*.[45] Symptoms of infection are nonspecific but include pruritus, vaginal discharge, and dysuria.

Unique Neonatal Manifestations.

Congenital cutaneous candidiasis is an uncommon clinical condition caused by an ascending infection into the uterus before birth. The infant at birth has a diffusely erythematous papular rash (Fig. 243.2).[46] The papular rash becomes pustular, followed by the development of vesicles and bullae. The rash also can manifest as bright red, "burn-like" dermatitis, and usually it is associated with positive cerebrospinal fluid (CSF), blood, and urine cultures. Infants weighing >1500 g most often have a benign clinical course. Systemic involvement is more likely in premature infants and frequently is associated with markedly elevated white blood cell counts (>100,000/mm^3). Risk factors for congenital cutaneous candidiasis include the presence of a maternal intrauterine device or cerclage placement.[47]

A second dermatologic manifestation in infants is invasive fungal dermatitis. Unlike congenital cutaneous candidiasis, lesions develop after birth but within the first 2 weeks of life (Fig. 243.3).[47] The skin is the point of entry for the organism, and risk factors for development include extreme prematurity, vaginal birth, hyperglycemia, and postnatal corticosteroid administration. The rash of invasive fungal dermatitis is erosive and crusting and is associated with a high incidence of positive blood cultures. Definitive diagnosis is made by biopsy.

Invasive *Candida* Infections

Candidemia or *Candida* BSI is defined as isolation of *Candida* from blood culture. Candidiasis describes all deep-seated *Candida* infections, including candidemia, as well as infections of single organs (e.g., liver, spleen, bone, brain). Candidiasis is rare in immunocompetent children. Infants with candidiasis typically are extremely premature, and children with candidiasis often are immunocompromised as a result of hematologic malignant disease, transplantation, or other primary or secondary immunodeficiency conditions. In addition to poor immunologic status, these patients commonly have multiple risk factors.

Signs and symptoms of *Candida* BSI often are nonspecific and subtle, especially in infants, and can include temperature instability, lethargy, apnea, hypotension, respiratory distress, abdominal distention, hyperglycemia, and feeding intolerance.[11,48] The presentation of candidemia cannot be readily distinguished from bacterial BSI. In immunocompromised children, *Candida* BSI often manifests as persistent fever despite antibiotic therapy. Presenting signs and symptoms can result from end-organ (central nervous system [CNS], renal, hepatic) dissemination following periods of BSI. Although prolonged candidemia is associated with increased risk of dissemination, dissemination can occur in the setting of only a single positive blood culture result.[11,49]

Meningoencephalitis.

Meningitis occurs in approximately 15% of infants with candidemia; this percentage represents a decrease since the 1980s, but it still is an excessive rate compared with adults with candidemia.[9] The decreased rate may reflect more aggressive use of empiric antifungal therapy. The incidence of meningitis in pediatric patients with cancer and candidemia also is higher than in their adult counterparts (11% vs. 1%).[50] This finding has important implications for diagnostic evaluation and therapeutic approaches because clinicians cannot assume a lack of CNS involvement in patients with seemingly simple candidemia.

Candidiasis of the CNS is more accurately described as meningoencephalitis because infection often results in granulomas, parenchymal abscesses, and vasculitis (Fig. 243.4). As a result, unremarkable CSF examination in the presence of CNS infection is common.[6,31] In 1 study, only 25% of infants with *Candida* meningitis had abnormal CSF.[28] Complications of CNS infections include obstructive hydrocephalus, calcifications, and thrombosis.[51] If CNS involvement is suspected or confirmed, imaging (ultrasonography, computed tomography, or magnetic resonance imaging) should be considered.

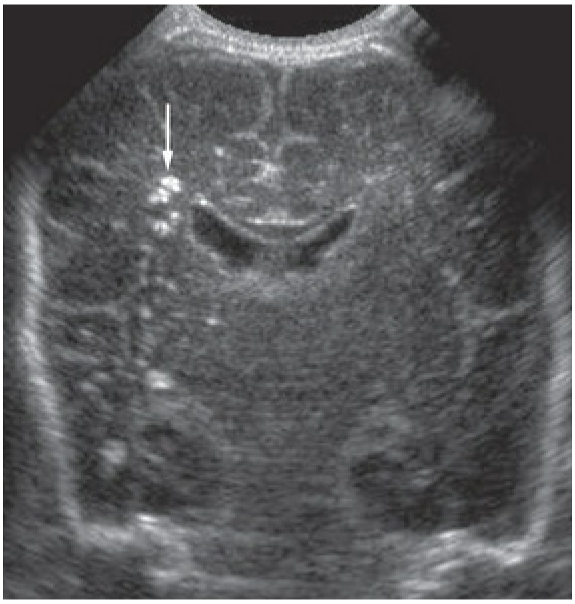

FIGURE 243.4 Cranial ultrasound scan showing fungal abscesses (*arrow*) seen as hyperechoic regions in a 22-day-old ex–25-week neonate with *Candida albicans* candidemia.

Renal and Urinary Tract Infections.

Renal *Candida* infections include candiduria, fungal debris within the renal collecting system, and renal parenchymal involvement (Fig. 243.5).[52] Renal disease can manifest as pyelonephritis, rising creatinine concentrations, hypertension, a flank mass, or acute urinary obstruction from fungal mycetoma.[53,54] In addition to severely immunocompromised patients, children with anatomic obstructions, congenital malformations of the urinary tract, or neurogenic bladder causing urinary stasis are at increased risk for *Candida* urinary tract infection.[52]

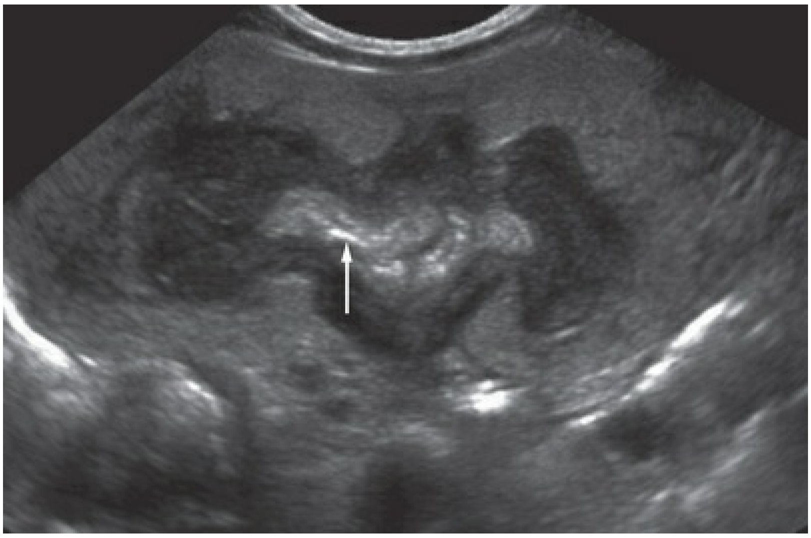

FIGURE 243.5 Renal ultrasound scan showing fungal abscess (*arrow*) seen as echogenic material within the renal collecting system of a 7-year-old child with acute myelogenous leukemia who was undergoing induction chemotherapy.

Patients with candiduria should have a renal ultrasound scan performed to evaluate for the 2 types of renal involvement: nonshadowing echogenic foci and parenchymal infiltration.[53] Findings can persist despite proper therapy, negative culture results, and clinical recovery.[55] However, caution must be used in interpreting ultrasound examination results because blood clots and renal stones also can resemble collections of infected material.[52,53] Fortunately, systemic antifungal therapy usually is sufficient treatment for renal involvement. Surgical intervention is indicated in patients with complete urinary obstruction.[53] Nonneutropenic patients with uncomplicated candiduria who have a Foley catheter in place should have the catheter removed or replaced and do not need systemic antifungal therapy.[56]

Optic Complications.

Optic infections can result in chorioretinal infections or, more rarely, lens abscesses.[57,58] The incidence of chorioretinal lesions complicating candidemia is decreasing.[59,60] Although chorioretinal lesions were found in 28% of adults with candidemia in 1 series,[61] only 1 patient with optic involvement was found among 123 VLBW infants with candidemia who were similarly studied.[59] In another study, no ocular findings were discovered in 30 children with candidemia.[62]

Infants with candidemia without direct optic infection are at increased risk for the development of severe retinopathy of prematurity.[29–31,57,63] Although the reason for this association is unclear, cytokines produced in reaction to the infection may play a role.[57] Because of the risk of endophthalmitis and the increased risk of severe retinopathy of prematurity, ophthalmologic examination should be considered in all infants with candidemia. Ophthalmologic examination for term and near-term infants with candidemia is especially important because they are not followed routinely for retinopathy of prematurity. Systemic antifungal therapy usually is sufficient for chorioretinal infections, but infections of the lens, an avascular structure, can require surgical treatment.[57,64]

Hepatosplenic Candidiasis.

Hepatosplenic candidiasis (also known as chronic disseminated candidiasis) (Figs. 243.6 and 243.7) occurs predominantly in patients with leukemia but can occur in any patient with candidemia. Children can come to medical attention with nausea and vomiting, right upper quadrant pain, hepatomegaly, or splenomegaly, often after recovery of immune function.[65] Blood culture results are positive in as few as 20% of patients with chronic disseminated candidiasis, and biopsy is considered the gold standard for diagnosis.[66] Treatment often lasts for months.

Other Affected Organs.

Endocarditis is documented in ≤5% patients with candidemia. Central vascular catheters can cause localized damage to the endocardium and increase the risk for endocarditis, especially in infants.[67,68] Other risk factors for *Candida* endocarditis in children include immunosuppression, congenital heart disease, and corrective surgical procedures for congenital heart disease.[68]

Candidemia also can result in infections of bones and joints, which can become evident days to weeks after control of BSI. Assessment of end-organ damage in the presence of neonatal candidemia should include an ultrasonogram of the head and abdomen, lumbar puncture, ophthalmologic examination, and an echocardiogram. Candidemia in a child should prompt a careful CNS examination, echocardiogram, and ophthalmologic examination.

Laboratory Findings and Diagnosis

Routine Tests.

Although white blood cell counts often are used as markers for systemic infections, only 60% of infants with candidiasis have abnormal counts.[5] Thrombocytopenia is a more sensitive marker, found in 84% of VLBW infants with candidemia.[69] However, the specificity of thrombocytopenia is low because other infections often cause thrombocytopenia.[69] Unexpected hyperglycemia can be associated with candidemia in neonates receiving parenteral alimentation.

Blood Culture.

The sensitivity of a standard bacterial culture typically is equivalent to that of a fungal culture. However, the sensitivity of either type of culture is lower for fungal compared with bacterial pathogens.[70–72] *Candida* species exhibit tissue tropism that often leads to deep organ involvement in the absence of prolonged candidemia. Blood culture sensitivity increases with increasing numbers of infected deep organs. In an adult autopsy study, sensitivity of blood culture was <30% with a single infected site but increased to 80% when 4 or more organs were involved.[71] Sensitivity of blood culture in pediatric patients is further compromised by the small amount of blood collected (as little as 0.5 mL in preterm infants vs. >10 mL in adult patients). Although sensitivity is poor, blood culture specificity approaches 100%. Isolation of *Candida* from a blood culture should not be considered a contaminant.

Polymerase chain reaction (PCR) allows for earlier identification of *Candida* species from positive blood cultures. Available PCR-based assays can identify certain yeast species from positive blood cultures with sensitivity and specificity >98%.[73–75]

Serologic Testing.

Serologic testing is seldom used for diagnosis of *Candida* infections.[76] Sensitivity is compromised in profoundly immunocompromised children with limited antibody production. Specificity also is low because colonized patients often produce antibodies.

Antigen Detection.

Limitations to antigen assays include rapid antigen removal by the immune system, use of polyclonal antibodies causing variability in results among assays, and poor assay sensitivity.[76] Moreover, several assays require the antigen to undergo processing by the immune system, and this processing may not occur reliably in immunocompromised patients. The 2 antigens used to detect *Candida* are (1,3)-β-D-glucan and mannan.

(1,3)-β-D-glucan is a cell wall component found in most species of *Candida* and can be detected in elevated amounts in serum of patients with invasive disease. When investigators used a cutoff value of 60 pg/mL, the assay demonstrated a sensitivity and specificity of 70% and 87%, respectively, in a series of 333 adult patients.[77] A meta-analysis including 19 studies found that (1-3)-β-D-glucan assays had a sensitivity of 81% and a specificity of 81% for diagnosis of invasive candidiasis, although most of the data were obtained from adults.[78] A retrospective examination of (1-3)-β-D-glucan levels in 61 infants with clinically suspected fungal infection found that the mean 1-3-β-D-glucan level was 364 pg/mL (range, 131–976 pg/mL) compared with 89 pg/mL (range, 30–127 pg/mL) among uninfected control infants.[79] However, the assay can produce many false-positive results.[80] False-positive test results can occur in patients receiving hemodialysis with a cellulose membrane and in samples exposed to gauze.[81,82]

Increasing numbers of patients are being evaluated with these newer molecular diagnostic tools, but to date no large pediatric or neonatal series have been conducted.[76,83] A second fungal antigen, mannan, has been found to correlate with invasive disease, but assays have limitations of low sensitivity and specificity. Assay sensitivity can be improved by testing at multiple time points. No pediatric studies have been conducted using *Candida* mannan antigen or antimannan antibody assays.

Fungal Metabolites.

D-Arabinitol, a sugar alcohol, is produced by *C. albicans, C. parapsilosis*, and *C. tropicalis*. D- and L-arabinitol are present in normal human urine and serum.[84] Ratios of serum D-arabinitol to creatinine were shown to correlate with antifungal treatment response in 10 of 10 adults with cancer.[85] In children with confirmed invasive candidiasis, the ratio of urinary D-arabinitol to L-arabinitol (DA/LA ratio) was elevated.[86] In a separate study, the urine DA/LA ratio was elevated in 6 infants infected with *C. albicans* compared with that of 40 healthy control infants.[84] Limitations of D-arabinitol as a diagnostic test include low specificity because colonized patients are known to have elevated D-arabinitol and creatinine levels, the need for gas chromatography mass spectrophotometry, and little or no D-arabinitol production by several pathogenic species of *Candida*.[87] At present, this test is not commercially available.

DNA Polymerase Chain Reaction.

PCR was both sensitive and specific for *Candida* in clinical specimens of adults as a qualitative diagnostic test in preliminary studies,[88] in which detected 1 colony-forming unit per milliliter of specimen.[89,90] Sensitivity of PCR as a diagnostic test is optimized by targeting ribosomal DNA genes, which contain highly conserved areas (18s, 5.8s, and 28s) separated by internal transcribed sequences (ITS1 and ITS2) containing variable, species-specific regions. These genes are present in multiple copies within the *Candida* genome and are an attractive target for amplification because the number of copies improves PCR assay sensitivity.[90]

Real-time PCR offers several advantages over conventional PCR techniques, including faster detection of amplicon as detection occurs during cycling and minimization of contamination because reaction vials do not have to be opened. Additionally, real-time PCR allows for the quantitation of the amount of starting DNA in the clinical sample, a feature that could aid assessment of response to antifungal therapy.[91]

Treatment

Thrush typically is treated with oral nystatin suspension. Azole antifungal agents (fluconazole, voriconazole) are alternatives. *Candida* dermatitis is treated with topical nystatin or miconazole. Candida vulvovaginitis is treated with topical antifungal formulations or oral azoles.

If a diagnosis of *Candida* BSI is confirmed in a patient with a central venous catheter (CVC) (tunneled, nontunneled, subcutaneously implanted, or peripherally inserted), the catheter should be removed as soon as possible and within 24 hours.[92] Delayed removal of CVCs consistently has been associated with increased mortality rates as well as morbidities, including poor neurodevelopmental outcome in infants.[10] Timely CVC removal is a critical tenet of management. Because of the extremely rapid development of *Candida* biofilms on catheters, a strategy to treat invasive candidiasis with a colonized catheter still in place is incorrect.

Few well-powered, randomized controlled trials have been conducted to establish treatment of candidiasis in children. A comparison of micafungin (2 mg/kg/day) with liposomal amphotericin B (3 mg/kg/day) found no difference in treatment success (i.e., 73% [35 of 48] for micafungin and 76% [38 of 50] for liposomal amphotericin B groups).[93] The incidence of adverse events was lower in the micafungin group (4%) compared with the liposomal amphotericin B group (17%). Length of therapy generally should be at least 3 weeks for infants because CNS involvement should be assumed. In older children, therapy should last at least 2 weeks following documented sterilization of the bloodstream.

Most clinically important species of *Candida* are susceptible to amphotericin B deoxycholate, with the exception of *C. lusitaniae* and occasionally *C. glabrata* and *C. krusei*.[94] Amphotericin B deoxycholate generally is better tolerated in infants compared with older children and adults.[95] Because immediate hypersensitivity reactions are less common in infants, test doses of the drug are not indicated in this population.[96] Lipid preparations of amphotericin B often are used because of renal insufficiency or in patients unable to tolerate amphotericin B deoxycholate; relatively increased doses of the parent drug can be administered with less associated toxicity. In the 1 randomized controlled trial of amphotericin B products in infants for the treatment of candidemia, 56 infants (including 36 ELBW infants) were given amphotericin B deoxycholate if their serum creatinine concentration was <1.2 mg/dL (n = 34) or either of 2 liposomal formulations (n = 22).[97] No statistically significant difference in mortality rates was noted among the 3 cohorts.

Flucytosine ([5-FC] Ancobon) is not an option as monotherapy for candidiasis because resistance develops rapidly. Use of 5-FC for candidiasis is further limited by adverse gut and bone marrow effects and by the lack of a parenteral formulation in the United States. The use of 5-FC in preterm infants is not recommended because of the immaturity of the preterm infant's kidney function and the need to monitor serum levels.[98] However, 5-FC occasionally is administered in combination with other agents for *Candida* meningoencephalitis because of its excellent CSF penetration and fungicidal activity.[99] In a cohort of 17 cases of *Candida* meningitis (including 11 infants), improvement was noted in 15 patients receiving combination therapy with amphotericin B deoxycholate and 5-FC.[100]

Fluconazole is commonly used to treat candidiasis in infants and pediatric patients.[101] The 2 most common species of *Candida* found in infants and pediatric patients, *C. albicans* and *C. parapsilosis*, are almost always susceptible to fluconazole. However, 50% of *C. glabrata* and 100% of *C. krusei* isolates are resistant to fluconazole.[102] Children >3 months of age require 12 mg/kg/day to achieve comparable adult treatment dose exposures, and they should likely receive a 25 mg/kg loading dose on the first day. In premature infants, a regimen of 12 mg/kg/day is necessary to achieve exposures similar to those in older children and adults,[103] and a loading dose of 25 mg/kg has been shown to achieve steady-state concentrations sooner than the traditional dosing scheme.[104,105]

Voriconazole has a wider spectrum of activity against *Candida* species than fluconazole and is active in vitro against some isolates of *C. glabrata* and *C. krusei* that are resistant to fluconazole. The pharmacokinetics of voriconazole has been described in children as young as 2 years of age (Table 243.1).[106–108]

TABLE 243.1

Dosing of Pediatric Antifungal Agents for Candidiasis

Drug	Formulation	Pediatric Dose	Infant Dose
POLYENES			
Amphotericin B deoxycholate	IV	0.5–1 mg/kg/day	1 mg/kg/day
TRIAZOLES			
Fluconazole	IV, PO	6–12 mg/kg/day	12 mg/kg/day (loading dose of 25 mg/kg)
Voriconazole	IV, PO	16 mg/kg/day divided q12h (9 mg/kg loading dose)	NA
ECHINOCANDINS			
Caspofungin	IV	50 mg/m^2/day (70 mg/m^2/day loading dose)	25 mg/m^2/day
Micafungin	IV	2–4 mg/kg/day	10 mg/kg/day
Anidulafungin	IV	1.5 mg/kg/day (3 mg/kg loading dose)	1.5 mg/kg/day (loading dose 3 mg/kg)

IV: intravenous; NA: not available; PO: oral.

Echinocandins (micafungin, anidulafungin, and caspofungin) are fungicidal for all clinically significant *Candida* species. Side effects are minimal in older patients, and the tolerability to this drug is superior to that of amphotericin B deoxycholate.[109] Studies have examined the pharmacokinetics of the echinocandins in children (see Table 243.1).[110–115] Although micafungin levels are undetectable in CSF,[116] the drug penetrates and cures invasive fungal infections in CNS tissue in animal models.[109] Higher systemic exposures in premature infants are thought to be important to drive the antifungal agent into the CNS.[117]

Special Considerations

Development of invasive candidiasis is the result of interactions among virulence factors of the *Candida* species, colonization burden, and host immunologic function. Specific risk factors for invasive disease tend to fall into 1 of 2 categories: those that increase colonization of mucosal surfaces or those that disrupt or impair immune function.[118]

Risk Factors Increasing Colonization

Infants initially are colonized by vertical transmission during birth or horizontally by parents or caregivers.[119,120] On admission to the NICU, 5% to 10% of all infants in 1 report were found to be colonized with *Candida* when cultures were taken from the oropharyx, skin, endotracheal tube aspirate, and rectum.[121] VLBW infants were found to be colonized at slightly higher rates. By 7 days of life, colonization rates increased to 50%, and they later rose to 64% by 1 month of age.[120,122,123]

After *Candida* colonization of the gastrointestinal tract and skin, any penetration of the mucosa, epithelial barrier through immature neonatal skin, or a device allows for hematogenous dissemination.[120,123,124] In a study of VLBW infants, invasive disease developed in 8% (3 of 39) with *Candida* colonization and in none of the noncolonized infants.[121] Endotracheal colonization has been associated with a sixfold increased risk of candidiasis.[122] In another neonatal study, a threefold increased risk of invasive disease was observed with each additional skin site of *Candida* colonization.[125] A study of pediatric liver transplant recipients also identified colonization as a risk factor for candidiasis.[126]

The use of broad-spectrum antibiotics enhances *Candida* colonization by eliminating competing bacterial flora.[6] In a cohort of more than 6000 infants, expanded-spectrum cephalosporin or carbapenem use in the previous 7 days was associated with candidiasis.[127]

High serum glucose levels provide substrate for fungal growth and are a reported risk factor for candidiasis in infants.[128] Hyperglycemia also can lead to upregulation of genes for adhesion proteins and proteins, thereby impairing the ability of complement to opsonize fungi.[129] Gastric acidity is considered protective against candidiasis by suppressing growth of *Candida* in the upper gastrointestinal tract. Acid-reducing drugs such as histamine-2 (H_2)–blocking and proton pump–inhibiting agents increase overgrowth of *Candida* in the gastrointestinal tract.[130] The use of H_2-blocking agents is linked to a risk of candidemia in infants,[23] and it also can increase the risk of infection by inhibiting neutrophil function.[131]

Risk Factors That Disrupt or Impair Immune Function

In almost every instance, candidiasis affects patients whose immune function is compromised. Prematurity is the strongest risk factor for invasive disease in infants. The immune system of the preterm infant has defects in chemotaxis, cytokine and antibody production, and phagocytosis.[49,132] In addition, the need for invasive medical devices such as a CVC and endotracheal tube further compromise the underdeveloped layer of skin.

Defects in neutrophil function or number are important risk factors for candidiasis in older children.[133,134] These neutrophil defects can be the result of primary immune defects (chronic granulomatous disease) or secondary defects (cytotoxic chemotherapy). The role of neutrophils in controlling *Candida* infections includes phagocytosis of organisms, as well as the elaboration of cytokines that stimulate other components of the immune system.[135]

The presence of a CVC, commonly used in immunocompromised patients, facilitates formation of a thrombin sheath to which *Candida* can adhere and replicate and that protects the growing fungus from host immune defenses. The presence of a CVC is associated with *Candida* BSI in both infants and children.[5,136] In addition, some *Candida* organisms., especially non-*albicans* species such as *C. parapsilosis* and C. *tropicalis*, produce a biofilm that provides additional protection from immunologic attack and antifungal drug activity.[137] Persistence of candidemia can be related to biofilm development. In 1 study, 100% (22 of 22) of *C. parapsilosis* isolates from adults with multiple positive blood culture results produced biofilms, compared with 62% (8 of 13) of isolates from patients with only 1 positive culture result.[137]

The use of corticosteroids such as hydrocortisone and dexamethasone is associated with an increased risk of candidiasis in infants and children.[50,138–140] Corticosteroids, in addition to suppressing immune function, can upregulate *Candida* virulence genes,[141] and corticosteroid-induced hyperglycemia also can predispose patients to infection.[20]

Among adult ICU patients, patients in surgical ICUs are at the greatest risk of candidiasis.[142] Abdominal surgical procedures that compromise the intestinal mucosal barrier can allow translocation of *Candida* into the bloodstream.[23,48,143] Surgical patients also are at heightened risk because of exposure to broad-spectrum antibiotics and the use of CVCs.[143]

Prevention

Nonabsorbable Oral Agents.

The use of nonabsorbable oral agents for the prevention of neonatal *Candida* BSI is controversial. A randomized controlled trial of 65 infants who were given nystatin or placebo demonstrated a significant decrease in both colonization rates and invasive *Candida* infections (6% in the nystatin group vs. 32% in the placebo group).[144] However, no difference in mortality rates or duration of hospitalization was noted, and interpretation of findings is confounded by the extremely high rate of *Candida* infection in the control group.[10,13] No decrease in candidiasis was observed in a placebo-controlled trial of 600 infants of <1750 g birth weight who were given oral miconazole gel.[145] In an analysis of >1700 infants weighing <1500 g at birth, the incidence of candidiasis was decreased with use of nystatin or miconazole therapy compared with placebo (4% vs. 23%; 95% confidence interval, 0.14–0.27).[146]

Fluconazole.

The pharmacokinetics of fluconazole makes it an attractive drug for prophylaxis. Fluconazole has good enteral absorption, excellent CSF penetration, and a long half-life allowing for long dosing intervals.[104] The drug is metabolized by the kidney and is excreted 80% unchanged in the urine.[147]

Several placebo-controlled trials have evaluated fluconazole prophylaxis in preterm infants. The first study enrolled 103 VLBW infants and demonstrated decreased rates of colonization but no difference in invasive disease.[123] The second study of 100 ELBW infants found a significant decrease in the incidence of candidiasis.[125] The placebo arm of this study had one of the highest rates (26%) of invasive candidiasis reported in ELBW infants, thus making the results and generalizability difficult to interpret. Neither study demonstrated a statistically significant survival benefit. A randomized multicenter study of 322 VLBW infants showed significant reductions in invasive candidiasis in fluconazole versus placebo recipients but no difference in all-cause mortality.[148] Again, the rate of candidiasis (13%) in the control group was much higher than reported generally. In a more recent placebo-controlled trial of 361 infants of <750 g birth weight, fluconazole (6 mg/kg twice weekly) decreased the incidence of candidiasis 3% versus 9% (P = 0.02).[149] No difference was observed in death or neurodevelopmental outcome between the 2 groups.

Studies of benefit of fluconazole (for prophylaxis in older children) also have shown mixed results. In a randomized study in children comparing oral fluconazole with oral nystatin in 50 children undergoing cancer chemotherapy,[150] 1 patient in the fluconazole group developed *Candida* colitis, and 1 patient in the fluconazole group and 2 patients in the nystatin group required empiric antifungal therapy.[150] A second, nonrandomized study of fluconazole prophylaxis in afebrile neutropenic pediatric patients demonstrated 3 breakthrough fungal infections among the 24 treated patients,[151] including 2 infections with fluconazole-resistant *Candida* species and 1 *Aspergillus* infection.

Key Points

Diagnosis and Management of *Candida* Infection

Epidemiology

- *Candida albicans* is the most common infecting species.
- Non-*albicans Candida* species are increasing as infecting species.

Clinical Features

- Certain patient populations (surgical intensive care, neutropenia) are at highest risk of invasive candidiasis.
- *Candida* meningoencephalitis is underdiagnosed in the neonatal population.

- Known neonatal risk factors for invasive candidiasis include cephalosporin or carbapenem use.

Diagnosis

- Blood cultures are the standard for diagnosis, but they are insensitive, especially in neonates because of low volume of samples.

- Negative culture results do not rule out disease definitively.

- Polymerase chain reaction and other molecular tests are in development.

Treatment

- Antifungal resistance is increasing, especially in non-*albicans Candida* species.

- Optimizing dosing of antifungal agents for pediatric patients is crucial.

- *Candida*-contaminated central venous catheters should be removed as soon as possible; biofilm formation begins rapidly.

Duration of Therapy

- Treatment for candidemia is at least for 21 days after first negative culture result in neonates and 14 days in children.

- Evaluation for dissemination to focal sites is prudent (see text).

Aspergillus Species

William J. Steinbach

Although yeasts such as *Candida* species are the most common causes of invasive fungal infections in children, *Aspergillus* infections are increasing and have a dismal mortality rate.[1–3] Invasive aspergillosis likely is gaining prominence because of more intensive chemotherapies for certain malignant diseases, immunosuppressive therapies for graft-versus-host disease (GvHD), increased use of mismatched or unrelated donor transplantations, newer preparative regimens to avoid graft rejection or disease relapse, and increases in early posttransplantation survival rates resulting from better control of bacterial and cytomegalovirus infections.[1,4]

Microbiology

The genus *Aspergillus* contains nearly 200 species, only approximately 2 dozen of which are known to cause human disease. Human disease is primarily caused by *A. fumigatus, A. flavus, A. niger, A. terreus*, and *A. nidulans*, with each species at times causing unique clinical infections. *A. fumigatus* is responsible for most cases of invasive and chronic aspergillosis,[5] specifically pulmonary, sinus, and central nervous system infection. Isolated sinus disease also can be caused by *A. niger* and *A. flavus*,[6] and ear disease in immunocompetent children often can result from infection with *A. niger*. A review of *Aspergillus* cultures found that amphotericin B–resistant *A. terreus* accounted for only 3% of cases of invasive aspergillosis, but it was found exclusively in cases of invasive disease and not in patients with colonization alone.[6]

The ecologic niche of *Aspergillus* species is the soil; the organisms especially thrive in compost, where they function as saprophytes growing on organic debris and recycling carbon and nitrogen throughout the environment.[7] Unlike the major pathogenic species *A. fumigatus*, *A. nidulans* is easily traceable genetically and often is studied as a laboratory model, yet translation of pathogenesis to *A. fumigatus* is unclear. Asexual reproduction in all *Aspergillus* species is abundant and is characterized by the production of green pigmented asexual conidia (spores). The conidia are produced in long chains radiating from phialides, and this reproductive structure is the derivation of the genus name *Aspergillus,* from the aspergillum used to spread holy water during the Roman Catholic Mass.

Aspergillus organisms aerosolize conidia, which immunocompetent people breathe harmlessly every day; it is estimated that most people inhale several hundred *A. fumigatus* conidia daily. Invasive infection in severely immunocompromised patients, or allergic or chronic infection in immunocompetent and less immunocompromised patients, usually is acquired through inhalation of airborne conidia. Two lines of host defense against *Aspergillus* exist, macrophages and neutrophils, and both are apparently required for resistance to invasive disease. The first defense is formed by alveolar macrophages; in vitro murine studies suggested that resident pulmonary macrophages are responsible for eliminating inhaled *Aspergillus* conidia from the lung.[8,9] If inhaled conidia escape, conidia germinate in the invasive *Aspergillus* hyphae and become susceptible to neutrophil release of toxic reactive oxygen species that are fungicidal.[10] The host can develop disease because of neutropenia, high challenge doses of conidia overcoming macrophages, or corticosteroid suppression of macrophage conidiacidal activity.[11]

A. fumigatus, in particular, is highly successful in colonization and invasion in immunocompromised patients. *A. fumigatus* has several characteristics that allow it to be a successful saprophyte and opportunistic pathogen. The ability to grow at 37°C is crucial for the development of human disease, and *A. fumigatus* is thermotolerant and thrives at human body temperature. Conidia are small (2.5–3 µm in diameter), thus permitting buoyancy in the air for prolonged periods and inhalation deep into the lung alveoli. When inhaled by an immunocompetent person, conidia rarely have deleterious effects because they are cleared by the phagocytic cells of the innate immune system. However, severe allergic disease can occur with repeated exposure to large doses of conidia.

Whole-genome sequencing of several *Aspergillus* species, coupled with newer proteomic techniques, has advanced understanding of pathogenesis. Various suspected putative *Aspergillus* virulence factors have been exhaustively reviewed,[12] and gene disruption studies have examined numerous varied gene products with little insight into true pathogenesis. Species of *Aspergillus* also are well known for their production of secondary metabolites, including the carcinogen aflatoxin produced by some strains of *A. flavus,* which plays an unclear role in human invasive fungal disease. The true virulence of *A. fumigatus* likely is multifactorial, and it likely also weighs heavily on the host's condition. Non-*fumigatus Aspergillus* species (e.g., *A. calidoustus, A. lentulus*, others) are increasing in incidence and carry worrisome antifungal resistance patterns.

Clinical Manifestations

Aspergillus produces a spectrum of disease, including allergic bronchopulmonary aspergillosis (ABPA), aspergilloma, chronic aspergillosis, and various forms of invasive aspergillosis.[12] The most common forms of invasive aspergillosis are acute pulmonary aspergillosis, acute invasive rhinosinusitis, cerebral aspergillosis, and disseminated disease. As with most invasive mold infections, the clinical signs and symptoms are nonspecific. Unfortunately, the most severely immunocompromised patients are those least likely to have symptoms, and in these patients diseases progresses most rapidly, whereas less severely immunocompromised patients (e.g., patients with diabetes mellitus or longterm corticosteroid use) usually have more indolent symptoms.[5]

Pulmonary Infection

Clinical manifestations in different patient populations have been reviewed,[5] but disease in most immunocompromised patients often is characterized by bilateral diffuse pulmonary infection (Fig. 244.1). The most common presentation is unremitting fever in a high-risk patient,[3] but high fever can be absent in patients receiving corticosteroid therapy.[13] Other early symptoms of pulmonary disease include a dry cough and possibly chest pain. Dyspnea is more common is patients with diffuse disease, and the presentation in some patients is similar to that of pulmonary embolism. Hemoptysis can occur and can be fatal as the first presenting episode,[14] whereas in neutropenic patients, pneumothorax also is an occasional presenting feature.[5]

The scan shows diffuse interstitial disease, with pleural thickening and soft tissue involvement on the left (arrow). Bronchoalveolar lavage culture grew *Aspergillus terreus.***

Invasive pulmonary aspergillosis is the leading cause of death in patients with chronic granulomatous disease (CGD), and it can be the first manifestation of CGD. Invasive aspergillosis in patients with CGD usually manifests within the first 20 years of life. Invasive aspergillosis in a child or adult without a known predisposing risk factor should prompt an evaluation for CGD. Patients with CGD can lack typical clinical symptoms (including being completely asymptomatic), or they can be afebrile and have only an elevated erythrocyte sedimentation rate. In a review of clinical findings at diagnosis of invasive aspergillosis in 23 patients with CGD, only one third of these patients were symptomatic, only one fifth were febrile; one half had a white blood count <10,000 cells/mm^3, and almost one half had an erythrocyte sedimentation rate <40 mm/hr.[15]

In early disease in a patient with CGD an acute neutrophilic response occurs, and neutrophils surround hyphae. However, hyphae remain intact as a result of impaired neutrophil-mediated killing. In this setting, pulmonary aspergillosis is a chronic progressive infection that can spread locally to involve pleura, vertebrae, and the chest wall (Fig. 244.2). In contrast to patients with neutropenia, in patients with CGD hyphal angioinvasion is not a feature of disease. The halo sign (angioinvasion with surrounding tissue ischemia), cavitated lesions, and pulmonary infarcts seen in neutropenic patients are not seen typically in CGD. Areas of tissue destruction are secondary to a reactive acute and granulomatous inflammatory process rather than directly related to growth of the hyphae.[16] Infection with *A. nidulans* is more common in patients with CGD; pulmonary disease is more likely to involve adjacent bone, more likely to cause disseminated disease, generally refractory to intensive antifungal therapy, and more likely to require surgical intervention in patients with CGD than in patients who do not have CGD.[17]

Invasive Sinusitis

Invasive *Aspergillus* sinusitis likely is underdiagnosed for lack of detailed examination, but patients can come to medical attention with ear pain or discharge, facial pain or swelling, localized pallor of the nasal septum or turbinate mucosa, epistaxis, orbital swelling, or headache.[5,13] The maxillary sinus is involved most commonly (Fig. 244.3), followed by the ethmoid, sphenoid, and frontal sinuses.[18] A careful rhinoscopic examination is needed to look for insensitive areas with decreased blood flow, frank crusting or ulceration, or blackened, necrotic foci. One study reviewed 11 patients with invasive fungal sinusitis after bone marrow transplantation, including 8 patients with *Aspergillus* infection. The mean interval from bone marrow transplantation to the diagnosis of fungal sinusitis was 22 days, and all patients had maxillary sinus involvement, one half also had ethmoid sinusitis involvement, and most patients had extension of the infection into the orbits, bone, or brain.[18] One major difficulty is the critically important diagnostic distinction between mucormycosis and aspergillosis, given the divergent therapeutic approaches. In a study evaluating pulmonary aspergillosis and pulmonary mucormycosis, concomitant sinusitis was significantly associated with mucormycosis and not aspergillosis in patients with radiographic evidence of pulmonary disease.[19]

Cerebral Infection

Cerebral involvement occurs in up to 40% of patients with invasive aspergillosis.[3,20] The pathogenesis is thought to involve hematogenous dissemination from an extracranial focus, most commonly the lung, or direct extension through the sinuses. *Aspergillus* hyphae are angioinvasive and thrombose arteries to create hemorrhagic infarcts, which then become abscesses (Fig. 244.4). Cerebral aspergillosis is the most common brain abscess type in hematopoietic stem cell transplant (HSCT) recipients; in 1 study 58% of brain abscesses were caused by *Aspergillus*, and 87% of these patients had concomitant pulmonary infection.[21] In another report of 18 patients with invasive aspergillosis, 10 patients had cerebral involvement, including 3 patients who presented with neurologic signs and no pulmonary symptoms.[22] The classic features of abscesses such as headache, nausea, and vomiting can be present in <10% of cases, with more prevalent features including altered mental status, confusion, hemiparesis, and cranial nerve palsies. Multiple lesions in the corticomedullary junction are consistent with infarct secondary to *Aspergillus* vasculopathy; dilated cortical vessels located in the central portion of the lesions in the corticomedullary junction are often distinctive signs of cerebral aspergillosis.[23] Definitive diagnosis requires a brain biopsy, but these patients often are too coagulopathic for the diagnostic operation.

Cutaneous Infection

Cutaneous aspergillosis can be either primary, usually from skin injury or traumatic inoculation, or secondary, from contiguous extension of hematogenous dissemination. In general, burn victims, neonates, and solid-organ transplant recipients develop cutaneous inoculation after prolonged local skin injury. HSCT recipients often develop secondary disease from contiguous extension of infected structures under the skin or from hematogenously disseminated embolic lesions.[24] In a review of >4000 patients with malignant disease, 15 had documented *Aspergillus* cutaneous infection,[25] whereas in another review, embolic skin lesions were present in approximately 11% of patients with disseminated aspergillosis.[26]

Cutaneous aspergillosis often begins as an area of raised erythema that progresses to include pain; skin involvement can be the first presenting sign of invasive infection.[27] The center of the lesion changes from red to purple, and then to black, and it can ulcerate.[5] Infections arising at the site of an intravenous catheter puncture typically begin with erythema and induration and progress to necrosis that extends radially.[28] Compared with wound mucormycosis, patients with primary cutaneous aspergillosis appear to present with significantly less local necrosis and systemic toxicity.[24]

Chronic Pulmonary Aspergillosis

Acute invasive aspergillosis occurs almost exclusively in patients with profound immunosuppression and displays rapid progression with poor outcome. However, some patients clearly have a more chronic *Aspergillus* infection. Chronic aspergillosis previously was known by several different terms, most notably *semi-invasive aspergillosis, chronic invasive pulmonary aspergillosis,* and *symptomatic pulmonary aspergilloma.* The blurred entity of chronic aspergillosis has been reclassified to include the following[29]: chronic cavitary pulmonary aspergillosis, in which imaging findings consist of the formation and expansion of multiple cavities, with some containing fungus balls; chronic fibrosing pulmonary aspergillosis, which denotes progress to marked and extensive pulmonary fibrosis; and chronic necrotizing pulmonary aspergillosis, or subacute invasive pulmonary aspergillosis. These patients have a mild or moderate defect in immune function, and their course is unlike that of patients with the other 2 chronic aspergillosis classifications in which a slow and progressive enlargement of an *Aspergillus*-containing cavity is noted. The diagnosis requires at least 3 months of pulmonary symptoms of chronic illness, radiologic abnormalities, and elevated *Aspergillus* immunoglobulin G (IgG) antibody or other microbiologic data. Surgery appears to play a smaller role in managing chronic aspergillosis, and the mainstay of treatment is longterm antifungal therapy to halt the progression of disease. Although no randomized clinical trial has been conducted to demonstrate the benefit of antifungal therapy in chronic aspergillosis, anecdotal evidence suggests slow improvement.[29]

Pulmonary Aspergilloma

Aspergilloma is considered a saprophytic, or noninvasive, form of infection in which *Aspergillus* colonizes preexisting pulmonary cavities caused by tuberculosis, sarcoidosis, bullous emphysema, bronchiectasis, or other conditions. Aspergilloma develops in approximately 15% to 25% of patients with cavitating lung disease resulting from tuberculosis.[30] Disease can be divided into simple and complex aspergillomas based on radiographic criteria. The simple aspergilloma can be differentiated from the complex aspergilloma by the absence of constitutional symptoms, paracystic lung opacities, cyst expansion, or progressive pleural thickening.[31] In a study of 62 cases of pulmonary aspergilloma, chest radiograph showed a "fungus ball" in the cavities of 42 (67%) and thickening of the cavity wall in 16 (26%) cases.[32] Patients with aspergilloma can be asymptomatic, but many patients have persistent and productive cough, hemoptysis, and weight loss. Surgical management to extricate the aspergilloma completely is the preferred treatment. Although the postoperative morbidity rate is higher in complex aspergilloma, in a series of 88 patients, surgical management led to nearly equivalent (80%) survival rates in patients with either simple or complex aspergilloma.[33] Medical management often is unsuccessful because penetrance of the antifungal agent into the cavity is poor. Percutaneous intracavitary instillation of antifungal therapy designed to fill the cavity and create an anaerobic environment for the *Aspergillus* has led to some success,[34] but it should be reserved for patients with inoperable cases.[35]

Allergic Bronchopulmonary Aspergillosis

ABPA is a hypersensitivity lung disease resulting from sensitization to environmental exposure to allergens of *A. fumigatus*. In this condition, *A. fumigatus* grows saprophytically to colonize the bronchial lumen and results in persistent bronchial inflammation. Conidia trigger an IgE-mediated allergic inflammatory response in the bronchial airways that leads to bronchial obstruction. ABPA is primarily a disease of patients with asthma (occurring in 1%–2%) or cystic fibrosis (1%–15%). Disease manifestations result from immunologic responses to the *A. fumigatus* antigens and include wheezing, pulmonary infiltrates, bronchiectasis, and fibrosis. Immunologic manifestations include peripheral blood eosinophilia, immediate cutaneous reactivity to *A. fumigatus* antigen, elevated total levels of serum IgE, presence of precipitating antibody to *A.*

fumigatus, and elevated specific serum IgE and IgG antibodies to *A. fumigatus*.[36]

The mainstay of therapy for ABPA is corticosteroid therapy for attenuation of the inflammation and immunologic activity, whereas antifungal therapy is used to decrease the fungal burden and therefore the antigen load. In a randomized, double-blind study, itraconazole was found to be superior to placebo for treatment of ABPA.[37] Although data are questionably sufficient to recommend itraconazole for initial therapy for ABPA exacerbation, itraconazole should be added to the therapeutic regimen if the patient has a slow or poor response to corticosteroids,[36] as part of a 2-armed approach to optimize therapy.

Epidemiology and Risk Factors

In a review of more than 5500 patients who underwent HSCT during a 15-year period, >7% had mold infections, including 342 patients with proven or probable *Aspergillus,* 31 patients with *Fusarium,* 29 with *Zygomycetes* (mucormycosis), and 10 with *Scedosporium* infections.[1] Aspergillosis is the leading cause of infectious death in HSCT recipients, and 1 study showed that 36% of all cases of confirmed nosocomial pneumonia in these patients were caused by *Aspergillus,* with an attendant crude mortality rate of 95%.[38] The incidence of *Aspergillus* infection in HSCT recipients has ranged from 3% to 7%,[14,20] but the true incidence likely depends on the follow-up duration of individual studies. In a retrospective review of 409 patients, 13% had invasive aspergillosis; *Aspergillus* accounted for 17% of all isolated pathogens in allogeneic transplant recipients and for nearly 4% in autologous transplant recipients.[39] A review of patients found an increasing incidence of invasive aspergillosis in both allogeneic transplant recipients (5% increasing to 12%) and autologous transplant recipients (1% increasing to 5%). The incidence of *Aspergillus* non-*fumigatus* species as the cause of invasive pulmonary disease also increased dramatically after 1995 (18% increasing to 34%).[1] In another study of HSCT recipients with invasive aspergillosis, the risk of developing the disease was 12.8 times higher among recipients of allogeneic than autologous HSCT.[40] The incidence of invasive aspergillosis is possibly higher in unrelated donors because of the more complicated immunobiology and more immunosuppressive treatment regimens required.

Aspergillosis in HSCT recipients has a well-characterized bimodal distribution that correlates with (1) pre-engraftment neutropenia with a median of 16 days and (2) the peak of GvHD with a median of 96 days.[41] This distribution likely relates to the 2 major mechanisms of protection against invasive aspergillosis: alveolar macrophages and neutrophils. Most patients with autologous transplants had a diagnosis of invasive aspergillosis while they were neutropenic, whereas patients with allogeneic transplants are at greatest risk of invasive aspergillosis after engraftment or during impairment of cell-mediated immunity secondary to cytomegalovirus or GvHD.[41] As early posttransplant management and survival improve, the peak of invasive aspergillosis appears to be shifting to the outpatient setting. In large reviews of patients undergoing allogeneic HSCT, invasive aspergillosis was diagnosed at a mean of 88 to 115 days after transplantation,[3,22,40,42] with a mortality rate exceeding 80%. In some studies, most cases were diagnosed after posttransplant day 30,[40,42] and in another study, no cases of invasive aspergillosis were diagnosed during the neutropenic period following transplantation.[43]

The risk of invasive aspergillosis is calculated to increase from 1%/day after the first 3 weeks of neutropenia to 4% to 5%/day after 5 weeks,[44] with a 70% incidence after neutropenia exceeding 34 days.[45] Risk associated with prolonged or marked macrophage dysfunctions leads to occurrence of invasive aspergillosis with advanced underlying disease, transplantation during relapse of malignant disease or chemotherapeutic rescue therapy, GvHD, or concurrent infection such as with cytomegalovirus.[44] In a survey of 24 medical centers with 148 patients who had invasive aspergillosis, 30% of these patients also had a bacterial infection, 20% also had a viral infection, and 19% also had another fungal infection.[6]

Numerous studies associate invasive aspergillosis with receipt of HSCT from a human leukocyte antigen (HLA)–mismatched or unrelated donor, as well as with underlying disease.[1,41] Corticosteroids are a well-known major risk factor and can suppress the ability of monocytes and macrophages to kill conidia through inhibition of nonoxidative processes and impairment of lysosomal activity. Corticosteroids also inhibit chemotaxis of polymorphonuclear neutrophils, oxidative bursts, and activity against hyphae.[46] Generally, corticosteroids suppress macrophages, whereas cytotoxic chemotherapies decrease neutrophil number and function. Corticosteroids also greatly accelerate the growth of *A. fumigatus;* in 1 study these drugs decreased the doubling time of this organism to only 48 minutes.[47]

In several studies of HSCT risk factors, only moderate to severe GvHD and corticosteroid prophylaxis for GvHD,[3,42,48,49] and total body irradiation,[48] were significant variables in the multivariate analyses. In 1 study, numerous factors in the period from HSCT to diagnosis of fungal infection influenced survival, and all these factors were related to the cumulative dose of prednisolone. In multivariate analysis, the relative risk of death from invasive aspergillosis was 8.8 in patients with acute active GvHD (≥grade 2) or extensive chronic GvHD combined with a cumulative total prednisolone dose of >7 mg/kg dose in the week before diagnosis.[3]

Few pediatric studies have examined risk factors for invasive aspergillosis. In 1 study, the highest incidence of invasive aspergillosis was seen in children who had undergone allogeneic bone marrow transplantation (4.5% occurrence rate) and in children with acute myelogenous leukemia (4% occurrence rate). Specifically, the incidence of invasive aspergillosis was significantly higher in patients with acute myelogenous leukemia than in those with lymphoblastic leukemia (relative risk, 5.6; 95% confidence interval, 4.6–7.0).[50]

Diagnosis

Culture

A definitive diagnosis of aspergillosis requires isolation of the mold from culture in addition to histologic demonstration.[51] The gold standard of tissue biopsy often is considered too invasive and can be complicated by bleeding or secondary infection in HSCT recipients. In a prospective study of 3857 clinical specimens from 230 patients, a mold was isolated from 86 patients, and 95% of these molds were *Aspergillus* species.[48] A 1-year retrospective study found that 12% of patients with positive culture results for *Aspergillus* met criteria for invasive aspergillosis. Among high-risk patients a positive culture result was associated with invasive aspergillosis in 50% to 65% of cases and among intermediate-risk patients in 8% to 28%, whereas patients with low risk rarely had invasive aspergillosis.[6]

In 1 study the predictive value of positive respiratory tract culture results was 40% to 100% for invasive pulmonary aspergillosis.[52] Even in patients with an established diagnosis, sputum specimen results commonly are negative,[13,53] likely because invasive pulmonary aspergillosis is predominantly infiltrative and does not have aerial growth in the bronchial tree.[13] Colonization with *Aspergillus* species has been a marker for reduced shortterm survival because 12% of colonized patients died within 3 months. Invasive pulmonary aspergillosis was diagnosed in 12% of patients with respiratory tract colonization, but this finding is likely an underestimate because the diagnosis often was made by radiographic imaging, and culture specimens were not always obtained.[6]

Aspergillosis rarely is diagnosed by blood culture. Investigators have speculated that only 32 cases of true *Aspergillus* fungemia have been correctly documented in patients with hematologic disease.[54] In a study of 1477 separate positive *Aspergillus* culture results, fewer than 20 blood culture results were positive, and most of these were associated with pseudofungemia or terminal events noted at autopsy.[6] In general, the *Aspergillus* hyphal mass that develops in the lumen during angioinvasion remains in place until the force of blood flow causes hyphal breakage, which then allows the mass to circulate. The likelihood is small that a blood culture would capture these irregularly and infrequently discharged units. This difficulty in detection of *A. fumigatus* in blood culture stands in contrast to other angioinvasive filamentous fungi (e.g., *Fusarium* species, *Paecilomyces lilacinus, Scedosporium prolificans, Acremonium* species) that can discharge into the bloodstream a steady series of unicellular spores, which are more likely to be captured in a blood sample. This ability to sporulate in tissue and blood has been termed *adventitious sporulation*.[55] Because *A. terreus* also displays adventitious sporulation, histopathologic and potassium hydroxide examination of these spores also can allow rapid, presumptive identification of *A. terreus*. Therefore a positive blood culture result with *A. terreus* or another fungus that demonstrates adventitious sporulation should not be ignored.

Imaging

A review of 27 pediatric patients showed that radiographic changes that developed after HSCT but before the diagnosis of pulmonary fungal infection included unilateral infiltrates (52%) slightly more often than bilateral infiltrates. At the onset, infiltrates were interstitial (41%), alveolar (41%), and mixed (18%). Hilar or mediastinal lymphadenopathy or pleural effusion or thickening was rare. By the time of diagnosis of pulmonary fungal infection the infiltrates usually were bilateral (66%) and alveolar or nodular (74%), including 22% of patients having cavitary lesions.[56] Invasive pulmonary aspergillosis characteristically manifests on radiographs as multiple, ill-defined, 1- to 3-cm peripheral nodules that gradually coalesce into larger masses or areas of subsegmental and segmental consolidation. Lobar or diffuse pulmonary consolidation is a common finding.[57] Although chest radiographs usually are abnormal, in 1 series radiographs were normal in approximately 30% of patients in the week preceding death.[58]

Invasive pulmonary aspergillosis has 2 classic radiologic signs. The halo sign occurs in neutropenic patients with a hemorrhagic nodule resulting from angioinvasion. An early computed tomography (CT) finding of the halo sign is a rim of ground-glass opacity surrounding the nodule. In 1 study, the halo sign was seen in all patients with biopsy-proven invasive pulmonary aspergillosis, but this sign is nonspecific and also is seen in patients with mucormycosis or entomophthoramycosis (formerly zygomycosis), organizing pneumonia, or pulmonary hemorrhage.[59] These early lesions subsequently change into a cavitary lesion or lesion with an air crescent sign 2 to 3 weeks after recovery of neutrophils.[57,60] In 1 study, the air crescent sign was seen in 48% of patients 3 to 10 days after recovery from neutropenia.[22] The appearance of the air crescent sign had no relationship with the duration of neutropenia, and it showed a tendency to appear in large lesions such as a consolidation or a mass rather than in small lesions such as nodules.[61] Cavitation of the nodules or masses occurs in approximately 40% of patients and is characterized by an intracavitary mass composed of sloughed lung and a surrounding rim of air. The use of CT has increased the sensitivity of radiologic diagnosis. In a study of 37 cases with invasive pulmonary aspergillosis the mean time to diagnosis in HSCT recipients was reduced from 7 days to 1.9 days by using chest CT.[62]

Radiologic differences for invasive aspergillosis can exist between adults and children. In adult series of pulmonary aspergillosis, approximately 50% of cases show cavitation, and 40% show air crescent formation.[63] In a 10-year review of pediatric patients (mean age, 5 years), central cavitation of small nodules occurred in only 25% of children, and no evidence of air crescent formation was noted within any area of consolidation.[64] In another pediatric report, the rate of cavitation on chest radiography[56] was 22% (6 of 27), and in another report the rate of cavitation by CT was 43% (6 of 14).[65] In these last 2 pediatric series, mean ages were older than in the other report of lower rates of cavitation and an absence of air crescent formation. This finding suggests a spectrum of radiologic findings related to age.

Findings by thoracic magnetic resonance imaging (MRI) are not as characteristic as CT findings, and the typical MRI sign is the target sign, a nodular lesion with a lower signal in the center compared with higher, contrast-enhancing signal intensity in the rim on T1-weighted images. This sign is highly suggestive of late-stage disease.[66] MRI is the modality of choice for diagnosing cerebral aspergillosis, and it is more sensitive than CT. Findings often show multiple lesions located in the basal ganglia that include an intermediate signal intensity, lack of contrast enhancement, and an absence of mass effect.[67] CT examination of the head often reveals 1 or multiple hypodense, well-demarcated lesions. Hemorrhage and mass effect are unusual, but for patients with adequate neutrophil counts ring enhancement and surrounding edema are more frequent.[5] In evaluating sinus disease, T2-weighted MRI images show markedly decreased signal intensity compared with images of bacterial sinusitis, which show increased signal intensity.[5]

Bronchoalveolar Lavage

The value of bronchoalveolar lavage (BAL) was analyzed in 23 consecutive patients with histologically proven invasive aspergillosis; only 7 patients (30%) had BAL specimens diagnostic for invasive aspergillosis. In the BAL-positive group, 71% had multiple changes on thoracic CT compared with 25% of patients with a negative BAL result. The diagnostic yield of BAL was not associated with clinical symptoms or the duration of neutropenia. A thorough review of the diagnostic yield of BAL specimens in histologically proven invasive aspergillosis yielded sensitivities of approximately 40% (range, 0%–67%),[68] but in 1 study BAL had a sensitivity of only 50% even in patients with focal invasive aspergillosis.[69] The sensitivity of respiratory tract culture specimens in general has ranged from 15% to 69%,[6] and in 1 study it increased to 50% to 70% in high-risk invasive aspergillosis groups. Therefore a negative BAL or respiratory culture result in a high-risk patient does not exclude the possibility of invasive aspergillosis.

Serologic Testing

Antibody Testing

Serologic testing for antibodies to *Aspergillus* antigens is helpful to diagnosis aspergilloma or ABPA in immunocompetent people, but unfortunately serologic testing plays little role in the immunocompromised patient because *Aspergillus* growth does not correlate with an increase in anti-*Aspergillus* antibody titers.[12] Serologic examination of 18 patients with invasive aspergillosis showed that anti-*Aspergillus* antibody detection was negative in all cases, likely as a result of profound immunosuppression.[22]

Galactomannan Antigen Testing

Galactomannan (GM) is a major cell wall component of *Aspergillus*. Highest serum concentrations of GM are released in terminal phases of the disease.[12] An enzyme immunosorbent assay (EIA) was introduced using a rat anti-GM monoclonal antibody, EB-A2, which recognizes the 1→5-β-D-galactofuranoside side chains of the GM molecule.[70] A sandwich EIA was introduced in 1995,[71] and by using the same antibody as both a capture and a detector antibody in the sandwich EIA (Platelia *Aspergillus*, Bio-Rad, Hercules, Calif), the threshold for detection can be lowered to 1 ng/mL. This sandwich EIA is the current commercially available assay.

The GM assay is positioned to detect only *Aspergillus*, but over the years reports have noted fungal cross-reactivity, more commonly with *Fusarium*, *Paecilomyces, Blastomyces, Histoplasma, Cryptococcus, Trichosporon*, *Penicillium*, and others. The GM cutoff value in serum adopted by the current international guidelines is an optical density index (ODI) of 0.5, and a meta-analysis found that the GM assay possesses an overall sensitivity of 71% and a specificity of 89% for invasive aspergillosis, highest in patients with hematologic malignant disease and HSCT recipients, but sensitivity drops to only 22% in solid-organ transplant recipients.[72] The GM assay is consistently most useful in patients with hematologic malignant disease who are undergoing chemotherapy and patients after HSCT, but it has high false-negative results in patients with CGD.[73] Sensitivity is greater in neutropenic patients, likely because of a more angioinvasive pathogenesis, and unfortunately it is low in the setting of mold-active antifungal therapy.[74] Previously, piperacillin-tazobactam was found to yield false-positive reactions with the GM assay; however, as a result of manufacturing changes, cross-reaction no longer occurs.

Serial testing at least twice a week during periods of high risk has been recommended.[75] In 1 study an increase in value during the first week of observation was predictive of progressive disease in allogeneic HSCT recipients.[76] In a large prospective study of hematology patients and HSCT recipients with confirmed or probable invasive aspergillosis, GM was detected in 65% of patients an average of 8.4 days before positive CT or culture results, and GM was detected in 40% of patients a mean of 6.9 days before the onset of clinical symptoms.

Diagnosis of pediatric invasive aspergillosis with the GM assay was once deemed impossible because earlier studies repeatedly showed a higher rate of false-positive results in children.[77,78] Theories to explain increased false positivity in children ranged from the presence of *Bifidobacterium bifidum* in the gut microflora that could mimic the epitope recognized by the EB-A2 in the EIA test[79] to GM-positive infant formula used in children.[80] However, more recent studies showed that the GM assay is very effective in children and has a low (1%–2%) false-positivity rate.[81,82]

The GM assay in BAL fluid seems to be more predictive of disease than the biomarker in serum. A large retrospective study of BAL GM found increased sensitivity with a cutoff value of 1, compared with the lower cutoff value of 0.5 in serum. This study also found that mean BAL GM was not different in neutropenic versus nonneutropenic patients, unlike the assay in sera.[83] A meta-analysis of BAL GM found an overall sensitivity of 90% and specificity of 94%. Additionally, antifungal therapy did not significantly affect BAL sensitivity, as is the case with serum samples.[84] In pediatric patients, a similar BAL GM cutoff value was established and suggested that a BAL GM >1 and a concurrent serum GM >0.5 yielded the overall best predictive value for disease.[85]

(1,3)-β-D-Glucan Testing

(1,3)-β-D-glucan is an integral cell wall component and, in contrast to GM, normally is not released from the fungal cell.[12] Factor G, a coagulation factor of the horseshoe crab, is a highly sensitive natural detector of (1,3)-β-D-glucan[86] through a modified limulus endotoxin assay. This assay is more nonspecific than the GM assay and detects several different fungi, including *Aspergillus* spp., *Candida* spp., *Fusarium* spp., *Trichosporon* spp., *Saccharomyces cerevisiae, Acremonium, Coccidioides immitis, Histoplasma capsulatum, Sporothrix schenckii*, and *Pneumocystis jirovecii*. The (1,3)-β-D-glucan assay does not detect *Cryptococcus* and the yeast form of *Blastomyces dermatitidis* (which produce low levels of [1,3]-β-D-glucan) or *Absidia*, *Mucor*, and *Rhizopus* (which produce no [1,3]-β-D-glucan). This assay does not identify the genus of the fungi detected, only the presence of the fungal call wall component. A meta-analysis of adult hematology and oncology patients determined that the sensitivity and specificity of 2 consecutive tests were 49.6% and 98.9%, respectively.[87]

In a study comparing (1,3)-β-D-glucan with GM, the sensitivity, specificity, and positive and negative predictive values for GM and β-glucan were identical. False-positive reactions occurred at a rate of 10.3% in both tests, but the patients showing false-positive results were different in each test. Both tests anticipated the clinical diagnosis and CT abnormalities, but the β-D-glucan test tended to become positive earlier than the GM test. A combination of the 2 tests improved the specificity (to 100%) and the positive predictive value (to 100%) of each individual test without affecting the sensitivity and negative predictive values.[88]

Another study compared GM, polymerase chain reaction (PCR), and (1,3)-β-D-glucan in patients with hematologic disorders; the receiver-operating characteristic analysis showed that the area under the curve was greatest for the GM assay, by using 2 consecutive positive results.[89] Unfortunately, (1,3)-β-D-glucan assay experience in children is limited to case series, so full operating characteristics of the assay in pediatric patients is not known.

Polymerase Chain Reaction

Efforts are focused on defining an optimal primer sequence for a PCR detection method for *Aspergillus*. No PCR assay is available commercially, and reports of performance can be difficult to interpret because of the lack of standardization among centers. Given the ubiquitous nature of the mold, the value of this test likely will be its high negative predictive value. Issues remaining unresolved in the use of PCR are the best source of material (e.g., whole blood, serum, plasma, BAL specimens), the amplification protocol (e.g., real-time, sample volume, extraction methods), and primer selection (e.g., "panfungal," 18S rRNA, 28S rRNA, mitochondrial DNA).[90] Using PCR for BAL specimens compared with blood samples seems less promising because of the high number of false-positive BAL results. Real-time PCR assays seem to decrease the risk of false-positive results and have better reliability than conventional PCR assays.[91] A meta-analysis of blood-based *Aspergillus* PCR in high-risk adult hematology patients found a sensitivity of 84% and a specificity of 76%, with specificity increasing to 94% with at least 2 positive PCR results.[92] In a subsequent meta-analysis of screening such patients by PCR and GM assays, the negative predictive value for invasive aspergillosis for both tests negative was 100%, and the positive predictive value of both tests positive was 88%.[93]

Treatment

For decades, the clinical response rate for invasive aspergillosis was only approximately 30% by using either amphotericin B or itraconazole treatment.[94] In a pivotal study comparing voriconazole with amphotericin B deoxycholate for initial therapy,[95] voriconazole had a statistically superior response rate (53%) versus amphotericin B (32%), with improved patient survival (71% vs. 58%). Although some investigators criticized this study for the use of other licensed antifungal agents after initial randomization to voriconazole or amphotericin B deoxycholate, a subsequent analysis revealed that the strategy of initial therapy with voriconazole also was superior to subsequent use of liposomal amphotericin B.[96] An additional open-label study confirmed the benefit of voriconazole as primary therapy versus salvage therapy,[97] thus highlighting the importance of using optimal antifungal therapy first.

Voriconazole now is the guideline-recommended primary therapy for all forms of invasive aspergillosis.[98] However, no defined optimal alternative is available in the case of recalcitrant disease or in the event of voriconazole side effects. If "salvage" therapy is required after the first agent fails clinically or unacceptable toxicities develop, options include therapeutic drug monitoring of voriconazole levels to document adequate exposure to the guideline-approved first agent, change of antifungal therapy likely to include a different class of agent, or the addition of another antifungal agent to use combination antifungal therapy. Above all, the correct diagnosis must be established.

Voriconazole trough levels do not correlate exactly with clinical outcome, and no universally accepted minimum standards exist. Although most experts would agree that a serum level should exceed the expected minimum inhibitory concentration for voriconazole of the infecting *Aspergillus* isolate (generally 0.5 μg/mL), different studies report the need for levels of at least 1.0 or 2.0 μg/mL. Because voriconazole pharmacokinetics clearly shows great interpatient variability, dosing and levels cannot be extrapolated easily among patients. However, individual patient consistency is reasonable, so therapeutic drug monitoring and trending in an individual patient are clinically helpful. The dosing of voriconazole in pediatric patients uses fundamentally different pharmacokinetics (linear in children vs. nonlinear in adults), and therefore dosing is increased in children (see Chapter 293).

Posaconazole is another triazole with excellent activity against *Aspergillus,* and a study demonstrated excellent activity as salvage therapy,[99] yet pediatric dosing has not been finalized. One option for failed voriconazole therapy is to change to a different class of agent; an amphotericin B agent or an echinocandin is an excellent option. A study comparing 2 doses of liposomal amphotericin B (3 mg/kg/day vs. 10 mg/kg/day) found no difference in clinical outcome, yet greater toxicity was associated with the higher amphotericin B dose.[100] The echinocandin antifungal agents appear to act primarily on the growing hyphal tip of the *Aspergillus*.[101] In the large open trial examining caspofungin as salvage therapy for invasive aspergillosis, a 45% (37 of 83) favorable response rate was reported,[102] suggesting an option for salvage therapy if initial antifungal therapy should fail. Micafungin also has been studied as an agent for invasive aspergillosis, with similar results.[103] Echinocandins, given their limited, fungistatic activity against *Aspergillus*, should not be used as primary monotherapy for invasive aspergillosis.

In the past, combination antifungal therapy for invasive aspergillosis was of little consequence because only a handful of possible agents or combinations was available, including the use of other agents such as rifampin and flucytosine, which are no longer recommended. However, the surge of newer antifungal drugs has created numerous potential combinations.[104] Although historical concerns of antagonism have been expressed, especially with the polyene-azole interaction, these concerns generally have not been clinically relevant.[94,104] Reports of both success and failure with combination antifungal therapy for invasive aspergillosis are myriad, mirroring the conflicting laboratory data ranging from antagonism to synergy. A combination trial with 454 patients comparing voriconazole versus voriconazole plus anidulafungin revealed that combination therapy, with the echinocandin delivered for the first 2 weeks of 6 weeks of total therapy, led to greater survival in certain subsets of patients.[105] Although the difference in mortality rate (19.3% vs. 27.5%) did not achieve the prespecified threshold for statistical superiority, secondary analyses tended to favor combination therapy. Whether the effect reflects that a second agent used immediately is therapeutic while the azole is reaching therapeutic levels (that often take a week) or represents a true antifungal synergy is unclear.

Surgery has value for treatment of local pulmonary aspergillosis, for patients with significant hemoptysis, and for lesions impinging on great vessels or major airways.[5,106,107] Bone marrow recovery induces cavitation, which creates a major risk of massive hemorrhage when the *Aspergillus* lesion is located near a main pulmonary artery or branch.[107] When marrow recovery occurs, the increased granulocytes release proteolytic enzymes at the site of infection, thus potentially damaging lung tissue. Radical debridement also is a crucial adjunct in sinusitis, and it can contribute to improved survival.

Prognosis

That the outcome of invasive aspergillosis absent immune reconstitution generally is poor highlights the paramount importance of recovery of immune function to survive. In parallel, decreasing immunosuppression (removing or lowering corticosteroids) is considered to be a helpful adjunct. The mortality rate associated with untreated invasive aspergillosis is nearly 100% in most patient groups, and the overall survival among patients treated with amphotericin B consistently had been approximately 34%,[108,109] but now generally it has improved to approximately 50%.[110] Cerebral disease is rapidly and almost uniformly fatal irrespective of treatment.[21] The prognosis for focal pulmonary aspergillosis is more favorable than that for diffuse bilateral disease because as focal disease tends to progress more slowly. However, focal disease carries an increased risk of hemoptysis, which often is life-threatening.[5] In 1 series, the median duration of survival of patients diagnosed with invasive aspergillosis was 29 days.[1] In another series median survival after invasive aspergillosis diagnosis was 36 days, with a 1-year survival rate estimated to be 22%, whereas mean survival for 11 patients with central nervous system disease was only 19 days.[3]

Key Points

Diagnosis and Management of *Aspergillus* Infection

Epidemiology

- *Aspergillus fumigatus* is the most common species causing infection.

- It is a ubiquitous mold in the soil.

Clinical Features

- Bimodal peak incidence of disease in stem cell transplant recipients: during periods of neutropenia and periods of graft-versus-host disease

- Increasing number of cases of invasive aspergillosis in nonclassically immunocompromised patients (e.g., chronic obstructive pulmonary disease, patients in intensive care)

- Pulmonary disease the most common clinical manifestation

- Pulmonary disease common and more indolent in patients with chronic granulomatous disease

Diagnosis

- High-resolution computed tomography is the imaging standard for pulmonary disease; magnetic resonance imaging is necessary for central nervous system disease.

- Serum galactomannan assay is the ideal noninvasive method; performance is best when patients are screened twice weekly during periods of greatest risk; bronchoalveolar lavage galactomannan assay is valuable and likely preferred over serum galactomannan assay if obtainable.

- Negative culture result on a bronchoalveolar lavage specimen does not exclude disease.

Treatment

- Voriconazole is the preferred antifungal agent for primary therapy.

- For salvage therapy, options consist of changing antifungal classes of therapeutic agent or adding another antifungal agent.

- Azole resistance is developing slowly.

- Optimal antifungal dosing is crucial in pediatric patients;

physicians should strongly consider measuring voriconazole levels.

Duration of Therapy

- Absent defined recommendations, at least 6 to 12 weeks is advisable.
- Therapy should be continued during periods of immunosuppression.

Agents of Hyalohyphomycosis and Phaeohyphomycosis

Thomas F. Patterson, Deanna A. Sutton

Agents of hyalohyphomycosis and phaeohyphomycosis are ubiquitous filamentous molds. (Moulds is the preferred spelling by many mycologists.) These molds are soil saprophytes and plant pathogens that have gained notoriety as emerging pathogens in immunocompromised hosts, including children. The pathogenesis of infections with these organisms is not clearly established because many of these organisms are minimally pathogenic in humans. However, these fungal conidia can cause infection in severely immunocompromised children, frequently in the paranasal sinuses or lungs, as a result of inhalation of aerosolized conidia.[1,2] Some of these organisms (e.g., *Fusarium* spp.) also can gain entry through the gastrointestinal tract, central venous catheters, or skin.[3,4] Direct inoculation of these organisms into tissues following trauma can lead to infection in both immunocompromised as well as immunocompetent children.[5–7]

Agents of Hyalohyphomycosis (*Fusarium, Scedosporium Boydii* Complex, *Paecilomyces,* and *Penicillium* Species)

Agents of hyalohyphomycosis are a diverse group of molds whose tissue form is hyaline. Colonies can be of various colors or lightly pigmented. The most important of these organisms is *Aspergillus* (see Chapter 244), but other molds, such as *Fusarium* species, the *Scedosporium boydii* species complex, *Chrysosporium* species, *Penicillium* species, *Paecilomyces,* and others, also cause infection in severely immunosuppressed children. These organisms resemble each other and *Aspergillus* in tissue, so cultures are needed to confirm the specific agent causing the disease.[8,9] As with other fungi, molecular and phenotypic studies have resulted in taxonomic changes in these molds; as a result, many molds are reported clinically as a species complex (e.g., *S. boydii* species complex and *Fusarium solani* species complex), which can contain a large number of distinct species.[10,11] The risk factors for these infections include significant immunosuppression such as immunosuppression associated with hematopoietic stem cell transplantation or bone marrow transplantation, profound neutropenia, malignant disease, and inherited immunodeficiencies.[12,13]

Epidemiology

Increasing numbers of agents of hyalohyphomycosis have been reported to cause invasive mycoses in severely immunosuppressed children.[14,15] The epidemiology and risk factors for infection with these agents are similar to those associated with *Aspergillus,* and the clinical presentations of these infections are similar to manifestations of invasive aspergillosis.[1,13] Clinical presentations include sinusitis, pulmonary infection, localized abscesses, cutaneous infection, and disseminated infection. Some of these infections have characteristic epidemiologic features, including infection with *Fusarium* species, which has been associated with inhalation of contaminated aerosols from hospital water as well as infection following a primary paronychial or skin infection.[1,3,16] In 2006, 164 confirmed cases of *Fusarium* keratitis were reported in wearers of soft contact lenses, and these infections led to corneal transplantation in 34%.[17,18] In a case-control study, cases were associated with use of a contact lens solution, although *Fusarium* was not found in unopened bottles.[17] *S. boydii* (*S. apiospermum*) infection has been reported in patients after an episode of near-drowning.[10,19,20]

Clinical Manifestations

Fusarium infections are among the most common of these agents, and they cause a spectrum of disease: toxin-mediated (mycotoxin syndrome), locally invasive, catheter-related, allergic bronchopulmonary, and disseminated infection. Toxin-mediated disease results from ingestion of contaminated grains. Symptoms range from mild gastroenteritis to bone marrow suppression resulting in aplasia and eventual death. Locally invasive diseases include mycotic keratitis, endophthalmitis, sinusitis, brain abscess, cystitis, cutaneous and subcutaneous infections, and paronychial and ungual infections.[12,13,21–23] Penetrating trauma has been associated with osteomyelitis and pyogenic arthritis. Locally invasive infections can occur in immunocompetent and immunocompromised hosts.[24–26]

Disseminated fusariosis, which is limited to immunocompromised hosts, especially hosts with a hematologic malignant disease or hematopoietic stem cell transplantation, is characterized by fungemia, skin lesions, and multiple organ involvement. Fungemia is detected in 50% to 60% of patients with a diagnosis of disseminated infection, and *Fusarium* is the only mold commonly associated with fungemia.[12] Skin lesions are macular or papular, often with a necrotic center, and they occur predominantly on extremities and are characteristic of this infection (Fig. 245.1).[3,23] Disseminated fusarial infection often is fatal; mortality rates between 60% and 100% are reported despite antifungal therapy, although improved rates of mortality have been reported since 2005.[13,27,28]

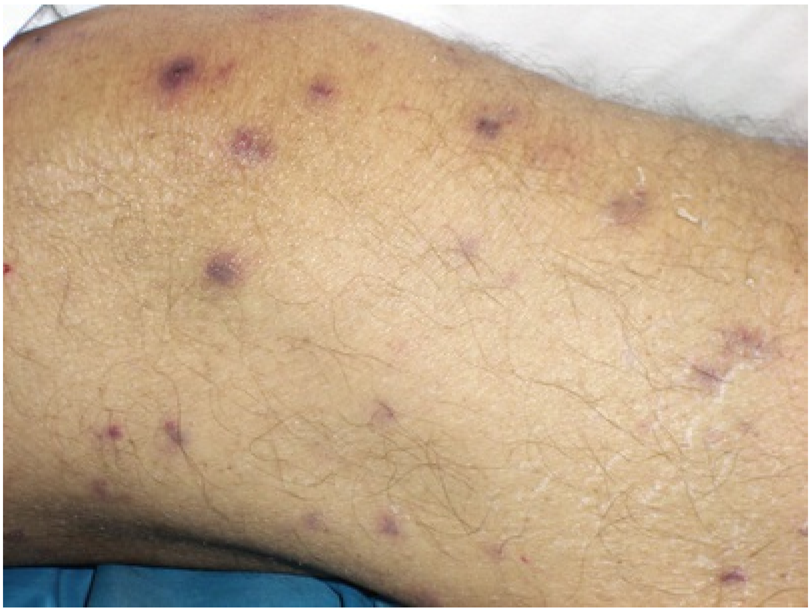

FIGURE 245.1 **Typical necrotic-appearing skin lesions of *Fusarium* infection on the arm of a patient with disseminated disease.**

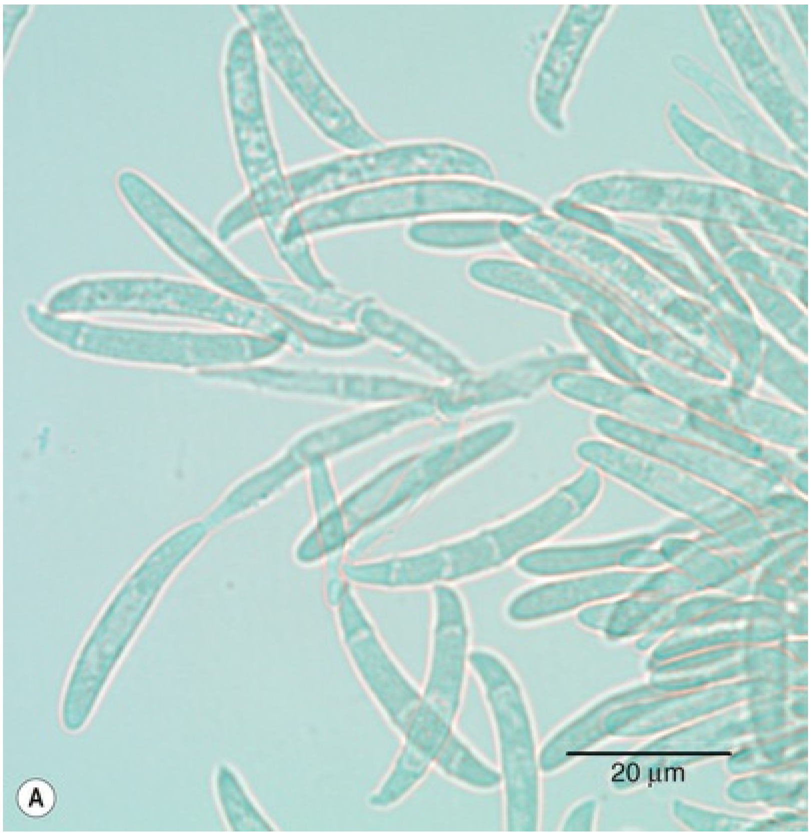
The *Scedosporium apiospermum* species complex consists of the closely related species *S. apiospermum* and *S. boydii*. These two species were previously considered to be the same species, with *S. apiospermum* being the asexual form (anamorph) and *Pseudallescheria boydii* being the sexual form (teleomorph). However, through phylogenetic analysis, it is now recognized that *S. apiospermum* and *S. boydii* (previously also referred to by the teleomorph name *P. boydii*) are indeed distinct species. Other sibling or cryptic species that are morphologically identical include *S. aurantiacum, S. dehoogii, S. minutispora,* and *S. desertorum*. In tissue, hylane, septate hyphae of *Scedosporium* resemble *Aspergillus* species. In immunocompetent hosts, these are major causes of fungal mycetoma, but in immunosuppressed hosts, widely disseminated infection occurs, including involvement of brain. These organisms can be resistant to amphotericin B, with variable activity of extended spectrum azoles, voriconazole and posaconazole, shown in adults and children.

Clinical manifestations of other hyalohyphomycoses are not distinctive and mimic those of invasive aspergillosis, including pulmonary infection, sinus infection, central nervous system disease, osteomyelitis, and locally invasive infections (e.g., keratitis and skin and soft tissue infections).

Laboratory Evaluation and Diagnosis

In tissue, all these organisms appear as branched, septated hyphae that are indistinguishable from hyphae of *Aspergillus* and other hyaline molds. Specific diagnosis requires isolation of the organism from culture of tissue (Fig. 245.2A). Some of these organisms are resistant to amphotericin B clinically and in vitro, including *Fusarium* and *S. boydii,* with better susceptibility reported to the newer azoles, voriconazole and posaconazole.[32,33] Blood cultures can be useful in *Fusarium,* but results are rarely positive with infection caused by other agents of hyalohyphomycosis. Serologic testing and non–culture-based methods such as polymerase chain reaction for these agents are not available commercially.



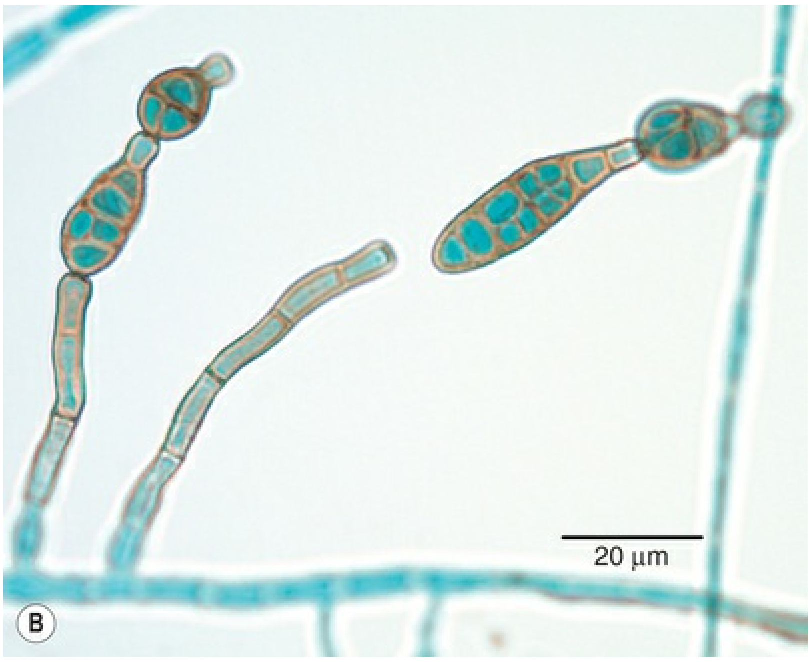


FIGURE 245.2 (A) Crescent-shaped macroconidia of *Fusarium* spp. (B) Club-shaped conidia of *Alternaria* spp.

Therapy and Prevention

Because some of these organisms, including *Fusarium* and *S. boydii,* are resistant to amphotericin B, responses to amphotericin B are poor, although successful outcomes with the use of lipid formulations of amphotericin B have been reported.[27,34,35] Posaconazole and voriconazole have been used with success in the treatment of both *S. boydii* and *Fusarium* infections and are the likely drugs of choice for the agents of hyalohyphomycosis.[4,31,32,36–38] With the use of voriconazole and liposomal amphotericin, better survival rates are being reported.[27] Similar responses have been reported with the salvage use of posaconazole. Itraconazole also has activity against many of these organisms, but because of variable bioavailability, the role of itraconazole is limited to children with less severe infection. Antifungal agents to prevent these mycoses are not specifically indicated because infection is rare, although prophylaxis with posaconazole has been shown to reduce *Aspergillus* infections and would presumably prevent the emergence of infections with these mycoses as well.[39,40]

Agents of Phaeohyphomycosis (*Bipolaris, Alternaria, Exophiala, Exoserohilum, Cladophialophora* Species, and *Scedosporium Prolificans*)

Agents of phaeohyphomycosis comprise a group of opportunistic molds that are dematiaceous (i.e., darkly pigmented in both tissue and culture).[7,9] Although phenotypic characteristics traditionally have been used to identify these organisms, molecular techniques have resulted in reclassification of many of these organisms, as well as the recognition of species complexes of distinct separate species. Examples of genera in this group include *Bipolaris, Alternaria, Scedosporium prolificans, Exophiala, Exserohilum, Cladosporium, Curvularia, Cladophialophora, Scopulariopsis,* and many others.[2,5,7,41–52] These emerging molds rarely are reported to cause infection in children.

Epidemiology

More than 150 and 70 genera of dematiaceous fungi have been implicated in human and animal disease, respectively; some of these fungi have been considered relatively nonpathogenic but can cause serious, even fatal, infection in severely immunocompromised children.[7] Some infections are associated with specific characteristics (e.g., *Cladophialophora bantiana* with a predilection for causing central nervous system infection), but generally these fungi do not cause syndromes specific to children.[2,4,7,53]

As with other molds, infection usually occurs by inhalation of conidia and generally starts in the sinuses or the lungs. Alternatively, infection can follow percutaneous inoculation and was associated with a large, multistate outbreak of *Exserohilum* meningitis caused by contaminated steroids.[2,6,54] Fungemia also can occur, although is less common compared with fusariosis.[55]

The organisms are found in decaying vegetation and are abundant in nature but of sufficiently low virulence that only scattered infections occur. These fungi thrive best in an acidic, glucose-rich environment and are killed by neutrophils. Neutropenia and uncontrolled diabetes are risk factors for infection. Traumatic inoculation from soil or plants is a major mode of infection.

Clinical Manifestations

The pathogenicity of agents of phaeohyphomycosis and the resulting clinical manifestations are quite variable. In immunocompetent children or children with minimal host defense abnormalities, phaeohyphomycosis can be associated with the development of sinusitis or pneumonia that can follow a subacute course developing over months to years, and direct invasion of brain from the sinuses can occur.[2,7,53] Infections can also have a significant component of hypersensitivity, with eosinophils and Charcot-Leyden crystals in sinus aspirates.

Locally invasive diseases include mycotic keratitis, paranasal sinusitis, osteomyelitis, and cutaneous infections. The paranasal sinuses are the most commonly infected sites, particularly in immunocompromised hosts with malignant disease. Characteristic lesions associated with sinonasal infections appear as superficial ulcers of the nasal septum, plaque-like necrotic lesions, and hemorrhagic crusts that are indistinguishable from lesions of aspergillosis or other fungi. Cutaneous lesions appear as nonhealing ulcerative or papular lesions with dry crusts. Subcutaneous lesions can enlarge gradually over months. Some organisms, such as *Cladophialophora, Verruconus* (previously known as *Ochroconis*) *gallopava, Rhinocladiella,* and others are neurotropic and cause brain abscesses.[7,55–57] Disseminated disease, including infection of the central nervous system, has been reported in severely compromised hosts, including children undergoing hematopoietic stem cell transplantation.

Laboratory Findings and Diagnosis

Agents of phaeohyphomycosis are characterized by the production of black melanin pigment, which can be seen histopathologically and in gross lesions. They are a diverse group of organisms characterized by septate, dematiaceous, branched, or unbranched fungal elements in tissue that can appear moniliform, bead-like, or swollen.[8,9] Species identification is made by examining conidia in culture (see Fig. 245.2B). Unfortunately, these mycoses can manifest in culture as *mycelia sterilia,* a mold culture that does not readily sporulate and thus does not allow identification. Masson-Fontana staining of tissue specimens is useful for staining the melanin in the hyphae and allows specific diagnosis of an agent of phaeohyphomycosis. Culture specimens are best obtained from normally sterile sites (e.g., biopsy of a subcutaneous lesion or sinus aspirate). These organisms can be found as commensals colonizing the respiratory tract from sputum samples, so a tissue biopsy may be needed to establish a diagnosis of invasive infection. Although blood culture results are rarely positive as compared with infections caused by *Fusarium,* fungemia can occur.[57]

Treatment and Prevention

Amphotericin B has been the common therapy for these infections. However, in vitro and in vivo activity of itraconazole and the extended-spectrum azoles, posaconazole and voriconazole, has been demonstrated against many of the agents of phaeohyphomycosis, so these drugs are possible alternatives, especially for longterm suppressive therapy.[4,58–60]

Although many of the black molds are susceptible to the extended-spectrum azoles, *S. prolificans* is a resistant pathogen.[2,31] The darkly pigmented *S. prolificans* (previously known as *S. inflatum*) is distinguished from the usually lightly pigmented *S. boydii* by the lack of sexual structures and the characteristic inflated conidiophore in the former. *S. prolificans* causes bone and soft tissue infections, as well as disseminated disease.[2] Outcomes are poor, even with treatment with the newer antifungal agents, thus often prompting attempts at combination therapy or local debridement.[61]

Voriconazole and posaconazole (usually used as salvage therapy) have been effective clinically in a few patients.[53,56,62] Itraconazole usually is reserved for patients with less severe infection.[63] Although pediatric doses of voriconazole or posaconazole are not established, voriconazole doses of 7 to 8 mg/kg every 12 hours intravenously have been suggested to give exposures similar to that of the usual adult dose (4 mg/kg every 12 hours). Posaconazole suspension typically has been started at 12 mg/kg/day in 2 to 4 divided doses but has largely been replaced by the extended-release tablet formulation, which is administered at doses of 300 mg/day following a 1-day loading dose of 300 mg times 2 doses for children 13 years of age and older. Therapeutic drug monitoring of both drugs should be useful to guide therapy. The echinocandins also have activity in vitro against some agents of phaeohyphomycosis, but clinical experience is limited, and these drugs are not recommended as single agents for therapy for these infections.[64,65]

No known ways exist to prevent infection with these unusual mycoses, although infection control efforts similar to those used to reduce risk of invasive aspergillosis are likely to reduce nosocomial airborne acquisition.

Key Points

Diagnosis and Management of Agents of Hyalohyphomycosis and Phaeohyphomycosis

Microbiology

- Agents of hyalohyphomycosis: molds that are hyaline in tissue; variously colored or light pigmented in culture, associated with soil, water, decomposing vegetation.

- Species include Aspergillus and other genera including *Fusarium, the Scedosporium boydii species complex, Paecilomyces, Chrysosporium, Penicillium,* and others

- Agents of phaeohyphomycosis: melanized or dematiaceous (darkly pigmented) molds or yeast-like fungi, associated with soil, water, decomposing vegetation.

- More than 150 species and 70 genera including *Bipolaris, Alternaria, Scedosporium prolificans, Exophiala, Exserohilum, Cladosporium, Curvularia, Cladophialophora, Scopulariopsis,* and others

- Many now referred to as a species complex because of the phylogenetic, phenotypic, and physiologic differences in strains

Epidemiology

- Occur worldwide, most commonly in severely immunocompromised children usually following inhalation of conidia

- Can follow direct inoculation from trauma or localized infection (keratitis, sinusitis, otitis)

- Specific exposures associated with some organisms (water aerosols for *Fusarium;* or near-drowning for *Pseudallescheria boydii* species complex; outbreaks caused by contaminated solutions: *Fusarium* keratitis and *Exserohilum* meningitis following injection of contaminated steroids)

Clinical Features

- Cutaneous infection: follows trauma in immunocompetent or compromised children; slowly increasing nodular or ulcerative lesions; also can reflect disseminated infection (fusariosis)

- Pulmonary: follows inhalation; including productive cough, fever, weight loss, shortness of breath, hemoptysis; nonspecific radiographic infiltrates

- Disseminated: severely immunocompromised children; neurotropism with brain abscess common for some organisms (agents of phaeohyphomycosis, e.g., *Cladophialophora bantiana*)

Diagnosis

- Recovery of organism from body fluids or tissue

- Microscopic examination of pathologic material: nonspecific histopathologic features for agents of hyalohyphomycosis; beaded irregular appearance of pigmented hyphae for agents of phaeohyphomycosis

- Melanin staining by Masson-Fontana method useful for agents of phaeohyphomycosis

Treatment

- Traditionally amphotericin B (or lipid formulation), but many species resistant to polyenes
- Activity and clinical use of voriconazole or posaconazole reported in case series; itraconazole reserved for less seriously ill patients

Agents of Mucormycosis

Thomas F. Patterson, Deanna A. Sutton

Mucormycosis (formerly zygomycosis) is an uncommon but emerging infection that occurs in immunocompromised patients, including children and neonates.[1–6] Previously, the term *zygomycosis* was used to refer to syndromes of mucormycosis and entomophthoramycosis, but updates in taxonomy determined that the class name Zygomycota is invalid.[7] Because the class Zygomycota no longer exists, the term *zygomycosis* has become obsolete.[1,7] Molds causing these infections are now in phylum Glomeromycota, subphyla Mucoromycotina and Entomophthoromycotina, respectively.[1,7] Infectious agents in the order Entomophthorales (e.g., *Conidiobolus* and *Basidiobolus*) produce distinct cutaneous and subcutaneous disease syndromes that are not discussed in this chapter.[8–11] Because clinically significant genera are in the subphylum Mucoromycotina, order Mucorales, the term *mucormycosis* is a useful clinical and valid mycologic reference.[1,7] Organisms in this order are characterized by the formation of broad, aseptate, or rarely septate hyphae and by sexual reproduction with formation of zygospores. The Mucorales are divided into 6 families of significance in human or animal disease, although most cases of human infection are caused by members of the family Mucoraceae. These families have undergone taxonomic revisions based on molecular, physiologic, and phylogenetic studies, including the reclassification of the family

Absidiaceae to Lichtheimiaceae for pathogenic species that are able to survive at temperatures of ≥37°C.[7,12] The family Mucoraceae produces *sporangiospores* (asexual spores) in a closed, sac-like structure called a *sporangium* that are released when the wall ruptures. The sporangium is attached to the hyphal substratum with a stalk-like structure, the *sporangiophore.* Different species are distinguished by the microscopic appearance of the sporangiophores, sporangia, and sporangiospores, as well as by the presence or absence of rhizoids (root-like structures) that anchor sporangiophores to the substratum.[13] In the family Mucoraceae, members of the genera *Rhizopus, Mucor, Actinomucor, Rhizomucor,* and *Apophysomyces* all have been implicated in human disease. Less frequently reported species in human disease in other families include *Cunninghamella, Saksenaea, Syncephalastrum, Cokermyces,* and *Lichtheimia*.[1]

The species isolated from cases of human infection are ubiquitous in decomposing organic matter such as spoiled bread, fruit, and other food items, as well as in soil. The most commonly encountered human pathogen is *Rhizopus ahhrizus* (*R. oryzae*), but many other species have been implicated.[3,6] All these organisms cause similar syndromes in children and neonates.[3–5]

Mucormycosis generally is acquired through inhalation of spores; the lungs and sinuses are the most common initial sites of infection. Less commonly, disease can arise after ingestion of contaminated foods or by direct inoculation following trauma or through vascular catheters, an important route of nosocomial transmission in neonates.[3,14] In an immunocompetent host, pulmonary macrophages ingest and kill inhaled sporangiospores.[15,16] In diabetic hosts and other immunosuppressed patients, macrophages fail to suppress spore germination.[17] Once infection is established, neutrophils have a pivotal role in killing hyphae. Severe neutropenia increases the risk of invasive infection, as does ketoacidosis in diabetic patients because of abnormal neutrophil function.[18]

Epidemiology

The spores of Mucorales are ubiquitous in the environment, but they only rarely cause infection without predisposing host factors.[6]

Certain predisposing conditions are associated with specific clinical manifestations of disease. For example, patients who have diabetic ketoacidosis typically have rhinocerebral mucormycosis. In patients with leukemia and other causes of neutropenia who are receiving cytotoxic chemotherapy, rhinocerebral, pulmonary, or disseminated disease can develop. Infants and children with severe malnutrition can have gastrointestinal tract mucormycosis.[5,19] Patients receiving deferoxamine for iron overload states also are at increased risk for mucormycosis.[6,15]

Prolonged neutropenia is well recognized as an important risk factor for mucormycosis among patients with leukemia and recipients of bone marrow or hematopoietic stem cell transplants.[20] Other contributing factors in these patients are the use of corticosteroids and broad-spectrum antibacterial agents.[3,5,21,22] Prolonged use of antifungal agents without activity against Mucorales (especially voriconazole, but also the echinocandins and fluconazole) in severely immunosuppressed patients has been reported as a risk factor for mucormycosis.[23–26]

In children, mucormycosis often develops in settings similar to those seen in adults, including neutropenia, solid-organ transplantation, hematopoietic stem cell or bone marrow transplantation, burns, and deferoxamine treatment for management of iron overload.[3,6] Infection occurs in distinct settings in children and neonates as well. These conditions include diabetes mellitus in children, particularly with uncontrolled diabetic ketoacidosis, and cutaneous infection in neonates.[3,14]

Nosocomial outbreaks of mucormycosis have been linked to construction work, as well as to contaminated air conditioning systems.[27] Nosocomial clusters of cutaneous infections, especially in neonates, have been traced to the use of contaminated biomedical devices (e.g., wooden tongue depressors) or have been associated with various adhesive bandages used in the hospital setting (e.g., elastic bandages or tape) and hospital linens.[28,29] However, because most cases of mucormycosis in hospitalized patients are sporadic, determining the site of inoculation or source of infection is difficult.[3,6]

Clinical Manifestations

Mucormycosis has several clinical presentations. Rhinocerebral and pulmonary infections are by far the most common. Other common clinical manifestations are gastrointestinal, cutaneous, and disseminated infection, which can include central nervous system involvement. Similar to other angioinvasive molds, a characteristic feature of mucormycosis is vascular invasion, which results in thrombosis, infarction, and necrosis of surrounding tissue. Mucormycosis often is characterized by the rapid onset of a necrotic lesion, followed by a fulminant course that requires rapid and aggressive medical and surgical therapy.

Rhinocerebral Infection

Rhinocerebral mucormycosis often begins with a necrotic lesion in the paranasal sinuses that then spreads to involve the orbit, face, palate, and brain. The disease classically occurs in patients with diabetic ketoacidosis, but it also can occur in patients with neutropenia and other immunocompromising conditions. Most commonly, rhinocerebral mucormycosis progresses rapidly and requires extensive surgical debridement combined with antifungal therapy.

Initial symptoms can include nasal or sinus congestion or pain, and epistaxis, along with fever. Black, necrotic lesions on the nasal or palatine mucosa are characteristic diagnostic signs, but the diagnosis often is not established early in infection. Infection can spread into the orbits and the periorbital or perinasal tissues and is associated with induration, necrosis, and edema. Ptosis, proptosis, dilation and fixation of the pupil, and loss of vision can occur. Infection can spread into the cavernous sinus and brain, with resulting abscess formation and necrosis of the frontal lobes.

Studies using computed tomography or magnetic resonance imaging are needed to assess the anatomic extent of suspected infection. The results of cerebrospinal fluid examination are nonspecific and do not assist in diagnosis.

Pulmonary Infection

Pulmonary mucormycosis is most common in severely neutropenic and other severely immunocompromised children, including children undergoing bone marrow or hematopoietic stem cell transplantation, particularly in the setting of graft-versus-host disease.[3,6,20,30] The clinical presentation usually is nonspecific and is similar to that of pneumonia caused by other angioinvasive molds (*Aspergillus*), and it can include pleuritic chest pain, cough, fever, and hemoptysis. The radiologic signs also can be nonspecific but include nodular lesions, cavitation, and a reversed halo sign which is characterized by a nodule with a central ground-glass attenuation encircled by a ring of denser consolidation that can be used to distinguish pulmonary mucormycosis radiologically from invasive pulmonary aspergillosis.[31] The mortality rate is high because of the unsuspected diagnosis in many patients, as well as the persistence of the underlying severe immunosuppression that predisposed the patient to infection.

Gastrointestinal Tract Infection

Mucormycosis of the gastrointestinal tract is rare but occurs in malnourished infants and children. In 1 review, 19 of 34 children with this condition were <1 year of age.[3,32] All segments of the gastrointestinal tract can be involved, but the most commonly affected sites are the stomach, large and small intestine, and esophagus.

Symptoms reflect the site affected but are not specific and include abdominal pain and hematemesis or gastrointestinal tract bleeding. Gastrointestinal mucormycosis can be complicated by perforation, perirenal abscess, and renal infarction. The course of the disease can be rapid, and survival is rare because of severe immunocompromise in the host and the difficulty in making the diagnosis.

Cutaneous Infection

Traumatic implantation of spores from soil can lead to extensive necrotic cutaneous infections.[33–37] Cutaneous mucormycosis has developed at the sites of surgical incisions and infected burn wounds.[2,3] *Rhizopus* spp. and other Mucorales organisms have caused necrotizing cellulitis in premature infants and children with leukemia in whom contaminated biomedical devices or adhesive products were applied to the skin near sites of catheter insertion or wounds.[29,30,35,38–40] Cutaneous infection with the emerging molds *Apophysomyces elegans* and *Saksenaea vasiformis* have been reported increasingly following traumatic inoculation in otherwise immunocompetent people, including children, especially following natural disasters (e.g., tornados) or from combat wounds.[3,36,37] These infections can be difficult to diagnose and identify because of the lack of growth from homogenized tissues and poor sporulation on routine media.[33,41–44] Children with leukemia also can have cutaneous lesions that result from hematogenous dissemination from another site.[3]

Cutaneous lesions typically begin with erythema and edema and progress to raised, indurated lesions with a black, necrotic center. Lesions are painful and are indistinguishable from those caused by *Aspergillus* or other molds, and they can resemble ecthyma gangrenosum. Cutaneous mucormycosis can progress rapidly, requiring extensive surgical debridement as well as optimal antifungal therapy.[2]

Disseminated Infection

Dissemination can follow any primary site of mucormycosis but usually is seen in severely neutropenic children after pulmonary infection.[3] The most frequent and feared site of dissemination is the brain, but metastatic necrotic lesions can occur in any organ. Cutaneous lesions can be an initial site of diagnosis that actually reflects disseminated infection.

Focal cerebral infection usually occurs in children as a result of disseminated infection, but in adults it also can occur as an isolated event in association with injecting drug abuse. The diagnosis of central nervous system mucormycosis is difficult but should be considered in a severely immunocompromised child with systemic mucormycosis who becomes lethargic, confused, or obtunded and is found to have a focal brain lesion on an imaging study.

Diagnosis

Early diagnosis of mucormycosis is essential for successful treatment. Unfortunately, the diagnosis of these infections is difficult because infection often is not suspected early in the course, blood culture results rarely are positive, and cultures of infected tissues are undertaken reluctantly. Non–culture-based methods are not available commercially, although various molecular tests are undergoing evaluation.[2] Agents of mucormycosis usually can be distinguished from other molds (e.g., *Aspergillus*) by their characteristic broad, rarely septate, or aseptate hyphae with right-angled branching. However, in histopathologic samples with only hyphal fragments identified, specific distinction can be difficult. Moreover, homogenization of tissue samples can render culture results for Mucorales negative. In patients suspected of having mucormycosis, communication between the clinician and the microbiologist to inoculate a nonhomogenized sample can increase the diagnostic yield.

Treatment

If treatment of mucormycosis is to be successful, the underlying immunologic or metabolic defects that precipitated the infection must be corrected, infected necrotic tissue must be debrided, and aggressive antifungal therapy must be administered.[2,3] Amphotericin B has consistent activity against Mucorales, but the toxicity of amphotericin B deoxycholate limits the drug's usefulness. Lipid formulations of amphotericin B and introduction of posaconazole, the first extended-spectrum azole with activity against these fungi, may reduce toxicity and improve outcomes of patients with mucormycoses.[45] Adjunctive measures should include surgical excision of infected tissues and discontinuation or reduction in immunosuppressive therapies or iron chelation treatment if possible. Hyperbaric oxygen therapy has been advocated by some investigators, but its efficacy remains unproven.[46–49]

Lipid formulations of amphotericin B (in doses ≥5 mg/kg/day) are less toxic than amphotericin B deoxycholate and are recommended as primary therapy in most patients.[1–3,45,49–53] Posaconazole has been shown to have activity in salvage therapy of mucormycosis and offers the advantage of longterm oral therapy, although previous oral solution formulations have very limited bioavailability.[54,55] Newer extended-release tablets are approved by the Food and Drug

Administration (FDA) for children >13 years of age at doses of 300 mg/day following a 1-day 300-mg loading dose for 2 doses, as indicated in adults.[56] An intravenous formulation has also been developed, although its safety and efficacy in pediatric patients have not been established. Additionally, isavuconazole, an extended-spectrum triazole with activity against many agents of mucormycosis as well as aspergillosis, has been released and is FDA approved for used in this infection in adults, although very limited evaluation has occurred in children.[57]

The duration of therapy depends on the clinical response, the extent of surgical excision, and the persistence of the underlying immunosuppression. Longterm oral therapy with posaconazole has been associated with a good response.[54,55]

The mortality rate of mucormycosis among patients with cancer remains high, despite faster diagnosis and aggressive surgical and antifungal treatment.[1,3,31,58] Although rates of successful salvage therapy with either posaconazole or liposomal amphotericin B are as high as 80%, the selection of patients to receive these agents likely influences these reported favorable response rates.[52,54,55] Better responses also occur in patients with infection that is surgically excised or debrided (e.g., isolated renal, cerebral, or cutaneous infection).

Prevention

Preventive measures should focus on reducing underlying risk factors that lead to the development of mucormycosis. These preventive measures include control of diabetes mellitus, the use of iron chelating agents other than deferoxamine, and limiting the use of aluminum-containing buffers in dialysis.[2,6,15] Limiting exposure of severely immunosuppressed patients to soil and plants, as well as the use of laminar air filtration and limitation of exposure to hospital construction, have been recommended to reduce the occurrence of aerosolization of molds, which include Mucorales.[59] The use of nonsterile items (which often become contaminated with environmental molds) on skin and mucous membranes in low birth weight infants and other immunocompromised patients should be avoided or initiated with caution.[30,39,60] In addition, reports of mucormycosis in patients receiving longterm prophylactic therapy with voriconazole raise concerns about the extended use of this drug in high-risk patients.[61] Although prophylaxis studies with posaconazole were not powered to show reduction in mucormycosis, consideration of posaconazole prophylaxis as a means of reducing mucormycosis and other mold infections in high-risk patients may be reasonable.[62,63]

Key Points

Diagnosis and Management of Mucormycosis

Microbiology

- Agents of mucormycosis: broad, aseptate, or rarely septate ribbon-like hyphae with right-angle branching
- Organisms now classified in the phylum Glomeromycota (which has replaced Zygomycota), subphylum Mucoromycotina; predominately in the order Mucorales so that mucormycosis is useful clinically and mycologically
- Order Mucorales with 6 families contains most agents of human disease. Taxonomic revisions reflect phylogenetic, phenotypic, and physiologic differences in strains including the reclassification of the family Absidiaceae to Lichtheimiaceae for pathogenic species that are able to survive at ≥37°C.
- Family Mucoraceae members (*Rhizopus, Mucor, Actinomucor, Rhizomucor,* and *Apophysomyces*) all implicated in human disease. Species in other families (*Cunninghamella, Saksenaea, Syncephalastrum, Cokermyces,* and *Lichtheimia*) less frequently reported in human disease

Epidemiology

- Spores of Mucorales are ubiquitous in the environment but usually cause infection only with predisposing host risk factors.
- Risk factors for infection include neutropenia, diabetes mellitus, ketoacidosis, iron overload, iron chelation, severe malnutrition, transplantation, corticosteroids, antifungal drugs without activity against agents of mucormycosis, burns, contaminated traumatic

wounds, and intravenous catheters.

Clinical INFECTIONS

- Cutaneous: associated with intravenous catheters and wound dressings; burns; traumatic implantation into normal children, especially with *Apophysomyces elegans* and *Saksenaea vasiformis*

- Pulmonary: usually in severely neutropenic children; nonspecific presentation following inhalation of organism including productive cough, fever, shortness of breath, hemoptysis; nonspecific infiltrates including reversed halo sign, which can help distinguish from invasive pulmonary aspergillosis

- Gastrointestinal: rare but occurs in malnourished infants and children; can affect any area of gastrointestinal tract with symptoms including perforation and abscess

- Rhinocerebral: classically associated with diabetic ketoacidosis, but occurs with prolonged neutropenia and immunocompromise; requires aggressive medical or surgical treatment

- Disseminated: in severely immunosuppressed children with prolonged neutropenia and in solid-organ or stem cell transplantation; high mortality rates, especially with central nervous system involvement

Diagnosis

- Recovery of organism from body fluids, tissue; no commercial non–culture-based methods; polymerase chain reaction methods in development

- Microscopic examination of pathologic material: broad, ribbon-like hyphae with few or no septations

- Cultures of nonhomogenized tissue can increase yield.

Treatment

- Polyenes (lipid formulations of amphotericin B) the drugs of choice; activity of posaconazole demonstrated in salvage trials and for longterm therapy; isavuconazole approved by the Food and Drug Administration but not studied in children

- Adjunctive therapy: echinocandins (can increase host responses, especially in combination therapy), hyperbaric oxygen, immune modulation, white blood cell infusion (all anecdotal)

- Preventive therapy: posaconazole presumed to have activity but not completely protective

Malassezia Species

Deanna A. Sutton, Thomas F. Patterson

Microbiology

Malassezia (formerly called *Pityrosporum*)[1] is a genus of lipophilic, basidiomycetous yeasts lacking ballistospores and classified in the order Malasseziales. Its phylogenetic placement within the Ustilaginomycotina (Basidiomycota) appears to be highly supported[2–5]; however, Hibbert's recent taxonomic treatment placing the order in the Ustilaginomycotina *incertae sedis* highlights its still somewhat unresolved phylogenetic placement.[6] *Malassezia* increasingly is recognized as an opportunist affecting both humans and animals.[7,8] Newer identification methods have made the characterization of several new species possible and also have enhanced our understanding of the ecology and clinical associations of the genus.[9] The genus is responsible for various superficial skin infections of humans, including pityriasis (tinea) versicolor (PV),[7,10,11] and *Malassezia* folliculitis (MF).[11] The association of *Malassezia* with seborrheic eczema/dermatitis also has been reconfirmed, although the implication of the immune system in this disease is critical.[7,12,13] Less commonly, members of the genus cause invasive disease in premature infants and other immunocompromised and debilitated individuals.[1] *Malassezia* species also have been implicated in atopic dermatitis, confluent and reticulate papillomatosis,[11] and neonatal cephalic pustulosis.[7,14,15] Various species of *Malassezia* form part of the normal microbial flora of the skin of humans and other warm-blooded animals, and most infections are endogenous in origin.

Until the 1990s only three *Malassezia* species were recognized: two lipid-dependent species, *M. furfur* and *M. sympodialis,* and one nonobligate lipophile, *M. pachydermatis.* After genomic and ribosomal sequence comparisons of a large number of human and animal isolates, the genus *Malassezia* was enlarged to seven species, consisting of the three former taxa (*M. furfur, M. pachydermatis,* and *M. sympodialis*) and four new taxa (*M. globosa, M. obtusa, M. restricta,* and *M. slooffiae*).[16] More recently, six new species have been described and reported: *M. dermatis,*[17] *M. japonica,*[18] *M. nana,*[19] *M. yamatoensis,*[20] *M. caprae,*[21] and *M. equina*[21,22], and *M. cuniculi*.[7] With the exception of *M. pachydermatis,* 13 of the 14 *Malassezia* species are lipid dependent. Their isolation in culture requires the use of a lipid-enriched culture medium. If a conventional medium is used (e.g., Sabouraud dextrose agar), the surface must be covered with a thin layer of sterile olive oil; however, this method yields recovery only of *M. furfur, M. pachydermatis,* and *M. yamatoensis*. Other selective media useful for a wider range of species include Dixon, modified Dixon, and Leeming and Notman agars.[23] *M. pachydermatis, which most commonly is not lipid dependent,* usually can be isolated on Sabouraud dextrose agar. The incubation temperature also is an important consideration because for many cutaneous species, the optimum growth temperature is 32°C to 34°C, rather than 37°C. Methods have been developed to separate the species of *Malassezia* on the basis of morphologic and physiologic differences; however, these are somewhat cumbersome, and species identification can be difficult. Commonly used physiologic tests include urease, catalase, and β-glucosidase activities, growth at 37°C and 40°C, and evaluation of growth in four water-soluble lipid supplements (Tweens 20, 40, 60, 80) and in Cremophor EL (castor oil) using a diffusion method in Sabouraud glucose agar.[24–27] The dependence on lipid precludes the use of conventional assimilation tests.

Molecular methods used to detect and characterize *Malassezia* species in humans and animals include biotyping using enzymatic methods, pulsed-field gel electrophoresis (PFGE), random amplification of polymorphic DNA (RAPD), DNA sequence analysis, restriction analysis of polymerase chain reaction (PCR) amplicon of ribosomal sequences, amplified fragment length polymorphism (AFLP), denaturing gradient gel electrophoresis

(DGGE), and terminal fragment length polymorphism (tFLP). These methods have confirmed the robustness of the new classification of *Malassezia* species, all species having their own characteristic karyotype.[28–31] DNA-based culture-independent methods, such as quantitative real-time PCR methods, can detect as few as 10 copies of *Malassezia* DNA and currently are the most reliable methods for detecting *Malassezia*.[31]

Although 14 species of *Malassezia* thus far have been recovered from humans and animals,[5] they do not appear to have equal clinical importance. Although many clinicians previously have considered all clinical isolates to be *M. furfur*, this assumption is no longer valid because the host, sources of infection, and routes of transmission vary by species.

Epidemiology

Malassezia species form part of the normal cutaneous flora of humans and other warm-blooded animals. The prevalence of skin colonization depends on age, anatomic site and, to a lesser extent, race. Cutaneous *Malassezia* is found immediately after birth. In a British study of skin swabs from 245 neonates, 31% were positive for *Malassezia*[32]; in 195 neonates from Iran, 68% tested positive, with a distribution of *M. furfur* and *M. globosa* of 60% and 7%, respectively.[33]

The incidence of skin colonization with *Malassezia* species increases with age, rising from about 25% in children to almost 100% in adolescents and adults.[34,35] The density of colonization in postpubertal people is greater in anatomic sites that contain pilosebaceous glands; *Malassezia* species have been isolated from 100% of samples taken from the back of adults, but from only 75% taken from the face and scalp. Studies have shown that the degree of colonization with *Malassezia* species is closely aligned with age-related changes in sebaceous gland activity,[34,36] and increased fatty acid concentration occurs primarily at puberty. PV is worldwide in distribution but most prevalent in hot, humid, tropical and subtropical climates, where 30% to 40% of the adult population can be affected.[8] In temperate climates the disease affects 1% to 4% of adults and is most common during the hot summer months. *Malassezia* folliculitis also is more prevalent in tropical countries and more common during the summer months in temperate regions.[8]

The precise conditions that lead to the development of PV and other forms of superficial *Malassezia* infection have not been defined, but host-specific adaptations are important factors because the transition from commensal to pathogenic states appears to be a continuum rather than a discrete entity.[7,37] The lesions of PV and seborrheic dermatitis have a predilection for anatomic sites that are well supplied with sebaceous glands, and patients with the latter condition have been shown to have higher concentrations of lipids on their skin than other individuals.[8] Instances in which members of the same family who are not cohabiting have demonstrated PV suggest a genetic predisposition. The higher incidence of *Malassezia* folliculitis and seborrheic dermatitis in people with immunosuppressive disorders, including AIDS, and in patients undergoing corticosteroid or other immunosuppressive treatment suggests that the relationship between *Malassezia* species and the immune system is important.

Exposure to lipid-rich intravenous infusions through a central venous catheter is the single most important risk factor for systemic *Malassezia* infection in both adults and infants.[38–46] Among neonates, other risk factors include low birth weight (LBW), early gestational age, and length of hospitalization. An investigation of one outbreak of *M. furfur* infection among LBW infants, most of whom received intravenous lipids, identified long duration of antimicrobial treatment as an additional risk factor for disease.[42]

Human-to-human transmission of *Malassezia* species is possible, either through direct contact or via contaminated clothing or bedding. In practice, however, cutaneous infection is endogenous in most cases, and spread from person to person is uncommon. No cases of occupational infection among healthcare personnel (HCP) have been reported.

Although most infections appear to be sporadic, healthcare-associated (HA) outbreaks of systemic *Malassezia* infection have been reported since the late 1980s in LBW infants and debilitated adults and children who were receiving parenteral lipid nutrition through indwelling vascular catheters.[40–44] An investigation of one outbreak of *M. furfur* infection among LBW infants provided evidence that the organism can be transmitted from an infected or a colonized infant to other infants by the hands of HCP.[42] HA outbreaks of *M. pachydermatis* infection also have been reported.[22–24] In one outbreak, patient-to-patient transmission of the organism was documented in a neonatal intensive care unit (NICU), but the source of the outbreak was not identified.[45] In another outbreak involving 15 infants in a NICU, *M. pachydermatis* was introduced into the unit on the hands of HCP who were colonized from pet dogs at home.[46] The organism persisted in the unit through patient-to-patient transmission.

Clinical Manifestations

Superficial Skin Disorders

Pityriasis Versicolor

A disfiguring but otherwise harmless condition, PV most commonly affects the trunk, neck, and upper portions of the arms. Although commonly ascribed to *M. furfur* under the old taxonomic classification, molecular studies have shown that most cases in northern countries are attributed to *M. globosa,* which is present in the yeast state on healthy adult skin but produces clinical lesions of PV after developing into the pseudohyphal state.[11] In tropical and subtropical climates, lesions more often are localized on the face and attributed to *M. furfur*. The characteristic lesions consist of patches of fine brown scaling that may become confluent and progress to cover large areas of the skin of the trunk and proximal extremities. Pruritus, which occurs in less than one third of adolescents and adults with PV, can be a prominent feature in young children. The disease is exacerbated by sunlight and sweating. Occasionally the rash has an inflammatory component, manifesting as erythema and fine vesicles. In light-skinned people, lesions are hyperpigmented and range in color from red to brown. In dark-skinned or tanned people, the lesions are hypopigmented and white. In contrast to adults, who seldom have facial involvement, prepubescent children with PV often have hypopigmented nummular lesions with fine scaling on the face.

In most cases the diagnosis of PV is made clinically. Hyperpigmented lesions must be distinguished from a number of conditions, including erythrasma, nevi, seborrheic dermatitis, and tinea corporis. Hypopigmented lesions can be confused with pityriasis alba and vitiligo. Wood light examination can be useful if the diagnosis is uncertain. On exposure to ultraviolet light, infected skin, particularly the scaly borders of the most recent lesions, emit a pale yellow fluorescence. If the diagnosis is in question, material for direct microscopic examination can be obtained by taking scrapings from the affected skin or by gently pressing transparent tape to the skin and then removing and examining the tape.

Malassezia Folliculitis

MF is a chronic disorder that primarily affects adults with a chronic debilitating disease and immunosuppressed people.[11,47] A minor outbreak of 11 cases of MF over 4 months was reported in an intensive care unit among cardiac transplant recipients.[48] MF also is seen quite often in people with AIDS. Little information is available about MF in infants and children. The typical lesions are small, erythematous, follicular papules that slowly enlarge and often become pustular. The condition often is associated with troublesome pruritus. Lesions occur on the back, chest, upper arms, and sometimes the neck, but seldom on the face. Pruritus and lack of comedones differentiate the condition from acne vulgaris. However, the two diseases often coexist, with nonitching acne lesions on the face and itching lesions of MF on the trunk and upper arms. It is sometimes necessary to perform a skin biopsy to make a definitive diagnosis. As with PV, *M. globosa* appears to be the predominant causative agent.[11]

Seborrheic Eczema/Dermatitis

The role of *Malassezia* species in seborrheic eczema (SE) or seborrheic dermatitis (SD) has previously been questioned; however, recent studies have reaffirmed its association.[12,49,50]

The clinical forms of seborrheic dermatitis include infantile seborrheic eczema on the scalp and trunk, and adult seborrheic eczema with an erythematous rash with scaling on the scalp, face, ears, chest, and upper part of the back. Dandruff is the mildest manifestation of the disease. Scaling of the eyelid margins and around the nasolabial folds is a common presentation. Itching is common on the scalp. The course of the disease is chronic, with regular flare-ups. In temperate climates the disease often improves during the summer months. The most common species associated with SE/SD include *M. globosa* and *M. restricta,* followed by *M. sympodialis, M. furfur,* and *M. slooffiae.*[26,51]

Systemic Infections

Systemic *Malassezia* infection has become a well-recognized complication of lipid-supplemented parenteral alimentation, and most cases occur in LBW infants younger than 1 month. Life-threatening systemic *Malassezia* infections have also been reported in older children and adults, all of whom received lipid emulsions through indwelling central venous catheters for periods ranging from a few days to many months. Predisposing diseases in this setting include Crohn disease, continuous ambulatory peritoneal dialysis, other chronic illnesses, invasive procedures, intensive care, and long-term antibiotic administration. Reported systemic infections range from localized organ infections to fulminant fungemia and death.

In infants, *Malassezia* fungemia can manifest with fever, apnea, or both, and bradycardia; interstitial pneumonia and thrombocytopenia are common. The most common symptoms of systemic infection are fever and respiratory distress with or without apnea. Less common symptoms and signs are poor feeding and hepatosplenomegaly. No signs of infection have been noted at catheter insertion sites, nor has rash been seen in infants with systemic *Malassezia* infection.

Predominant pathologic changes in patients with systemic *Malassezia* infection involve the heart and lungs and include mycotic thrombi around the tips of indwelling catheters, vegetations on the endocardium, vasculitis, and inflammation of alveoli, bronchi, and bronchioles. Predominant organisms in invasive disease include *M. furfur* and *M. pachydermatis.*

Diagnosis

Superficial Infections

Direct microscopic examination of scrapings from lesions usually is sufficient to permit the diagnosis of PV if clusters of round or oval budding yeast cells and short, seldom-branching pseudohyphae are seen. Because *Malassezia* species are part of the normal cutaneous flora, their isolation in culture must be correlated with clinical findings. Additionally, with the exception of most strains of *M. pachydermatis*, these organisms cannot be isolated on routine mycologic media unless lipid is added. In MF, microscopic examination of biopsy specimens reveals inflammatory cell infiltration of the pilosebaceous apparatus, keratin plugging, and round, budding yeast cells in the dilated hair follicles.

DNA-based, culture-independent molecular methods (e.g., quantitative real-time PCR methods) are the most reliable for detecting *Malassezia* in skin samples.[31] Isolates from nosocomial outbreaks can be analyzed by molecular tools to confirm strain identity.[38,39]

Systemic Infections

The diagnosis of *Malassezia* septicemia should be considered in any febrile patient (particularly with clinical and radiologic evidence of pneumonia) receiving lipid-containing alimentation through a central venous catheter, especially if the results of routine blood cultures are sterile. If the catheter can be removed, the tip of the catheter should be inoculated onto Sabouraud dextrose agar overlaid with olive oil or another medium supplemented with long-chain lipids. When catheter removal is not feasible, blood for culture is obtained through it. The lipid concentration of conventional broth and agar media usually is insufficient to support the growth of *Malassezia* species (with the exception of *M. pachydermatis*), but it would appear that the blood of patients receiving parenteral alimentation often contains sufficient lipids to support initial growth of these organisms in culture. Although the yield is low, microscopic examination of Giemsa-stained smears of blood obtained through the catheter may be helpful.

Treatment

Skin Infections

In most patients, PV responds to topical treatment, but more than 50% experience relapse within 12 months. Selenium sulfide lotion (2.5%) should be applied to the lesions for 15 to 30 minutes nightly for 1 to 2 weeks and then once monthly to prevent recurrences. Ketoconazole shampoo is applied for 3 to 5 minutes once daily for 5 days. For extensive involvement in adolescents, or in infections unresponsive to topical therapy, both itraconazole (200 mg once daily for 1 week) and ketoconazole (200 mg once daily for 1 week) are effective oral treatments, although oral ketoconazole cannot be recommended because of its greater potential for severe toxicity.

Treatment with a topical imidazole or selenium sulfide often is effective in MF, but oral treatment with ketoconazole (in doses of 200 mg/day for 1 to 2 weeks) may be required in patients with extensive or recalcitrant lesions. To prevent recurrence, maintenance treatment should be given once or twice a week. Ketoconazole shampoo, used twice a week for 2 to 4 weeks, is an effective treatment for seborrheic dermatitis and dandruff of the scalp. Thereafter, it should be used at 1- or 2-week intervals to prevent recurrence. Oral azole therapy for 1 to 2 weeks should be reserved for cases that do not respond to topical treatment. Ciclopirox olamine 1% shampoo also appears to be a safe agent for treatment of scalp SD.[52]

Systemic Infections

The most important factor in successful management of *Malassezia* fungemia in preterm infants and in older children is prompt removal of the colonized vascular catheter. Lipid supplements should be discontinued in almost all patients, and an antifungal azole agent, such as parenteral fluconazole (in doses of 5 mg/kg/day) or amphotericin B, should be administered to those with more serious infection.[38] The extended spectrum azoles, voriconazole and posaconazole, have in vitro activity, but clinical data on their efficacy are extremely limited. No data support the activity of echinocandins against these basidiomycetous yeasts. Oral fluconazole or itraconazole may be adequate therapy for less ill patients. The duration of therapy depends on persistence of the fungemia, the presence of metastatic foci of infection, and removal of the catheter. In vitro antifungal susceptibility testing of *Malassezia* species is unstandardized because of its dependency on lipid for growth; however, several methods have been published.[38,53–55] These methods, which test a variety of species (*M. furfur, M. dermatis, M. globosa, M. obtuse, M. restricta, M. slooffiae, M. sympodialis,* and *M. pachydermatis)* against several antifungal agents (amphotericin B, itraconazole, ketoconazole, fluconazole, voriconazole, posaconazole, and terbinafine), demonstrate species-dependent in vitro data, reporting higher minimal inhibitory concentrations (MICs) for fluconazole for some *M. pachydermatis* isolates.

Key Points

Diagnosis and Management of *Malassezia* Infections

Microbiology

- Lipophilic, basidiomycetous yeasts in the order Malasseziales
- Genus includes 14 species, 13 of which require lipid-enriched culture medium for growth.
- *M. pachydermatis* is not lipid dependent.

Epidemiology

- *Malassezia* is part of the normal flora of humans and warm-blooded animals.
- Skin colonization begins at birth, increases to 25% in children, and reaches almost 100% in adults.
- Degree of colonization is related to sebaceous gland activity at puberty.
- Lipid-rich intravenous infusions are an important risk factor for systemic disease.
- Most infections are sporadic, although nosocomial systemic outbreaks have been reported.

Clinical Features

- Superficial skin disorders

  - Pityriasis versicolor: commonly affects trunk, neck, upper arms; lesions are hyperpigmented in light-skinned people and hypopigmented in dark-skinned people.

  - *Malassezia* folliculitis: primarily affects adults with debilitating disease; lesions are small, erythematous, follicular papules that often enlarge and become pustular.

  - Seborrheic eczema/dermatitis: clinical forms include infantile and adult seborrheic eczema; dandruff is the mildest manifestation.

- Systemic infections: severity ranges from localized organ infection to fulminant fungemia.

Diagnosis

- Superficial infections – direct microscopic examination of lesions, culture with special media and/or lipid overlay, molecular methods, including matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry analysis

- Systemic infections – cultures of central venous catheter and blood (require lipid supplementation and may require long incubation times [up to 2 weeks]), and molecular methods

Treatment

- Skin infections

  - Pityriasis versicolor: topical selenium sulfide lotion 2.5% or oral azole

  - *Malassezia* folliculitis: topical imidazole or selenium sulfide; oral azole may be required; maintenance treatment may be required to prevent recurrence.

- Seborrheic dermatitis: ketoconazole shampoo or ciclopirox olamine 1% shampoo usually is effective; oral azole for recalcitrant infections.

- Systemic infections

- Remove vascular catheter promptly in preterm infants with fungemia; discontinue lipid supplements; fluconazole is the preferred antifungal, and amphotericin B is reserved for more severe disease.

- In vitro activity of various antifungal agents is species dependent; higher minimal inhibitory concentrations (MICs) for fluconazole for *M. pachydermatis*.

Sporothrix schenckii Complex (Sporotrichosis)

Thomas F. Patterson, Deanna A. Sutton

Sporotrichosis is a chronic subcutaneous fungal infection caused by thermally dimorphic fungal species in the *Sporothrix schenckii* complex. This species complex is found worldwide in soil, on decomposing vegetation, and on plant material, such as sphagnum moss, hay bales, rosebushes, and wood. In nature, *S. schenckii* grows as a filamentous mold, but in tissue it forms small budding yeast cells. Sporotrichosis has a worldwide distribution but is most common in warm, temperate, or tropical regions where the temperature ranges between 16°C and 22°C.

Phylogenetic, phenotypic, and physiologic differences have been identified among strains previously referred to as *Sporothrix schenckii;* therefore, isolates now are reported as members of the *S. schenckii* complex.[1,2] In addition to *S. schenckii,* other distinct species in the complex include *S. mexicana, S. globosa, S. luriei, S. albicans, S. inflata,* and *S. brasiliensis.*[1,2,3] The typical rosettes produced by these species are mostly indistinguishable; however, the sessile conidia display varying morphologies. *S. luriei* lacks sessile conidia and has a thick-walled budding yeast form.[3] Calmodulin gene sequences are the most informative for species identification.[3] Varied in vitro susceptibility may be responsible for varying clinical responses.[4]

Epidemiology

Cutaneous infection, the most common manifestation in children and adults, usually follows traumatic implantation of *S. schenckii.*[5] Minor trauma from thorns or wood splinters is a typical route of exposure. Lesions usually appear 1 to 4 weeks after inoculation. Pulmonary disease is less common but is acquired by inhalation. Animal-to-human transmission, usually from cats with lesions, can occur but is not common, although large outbreaks associated with cats have occurred; transmission from other animals, including armadillos, also has been reported.[6–8]

Infection with *S. schenckii* complex occurs in all age groups, independent of race and gender, although some studies report a male predominance, possibly because of a higher number of exposures. Infections often are sporadic, occurring after outdoor exposures, although common-source outbreaks are described and can be traced to activities that result in contact with contaminated moss, hay, or wood.[9–12] Ongoing zoonotic transmission from cats has been associated with epidemics of sporotrichosis in Brazil, Malaysia, and other regions.[7,8,13–15] Investigation of outbreaks has led to insights into the epidemiology of sporotrichosis in the epidemic setting, but less information is available about the disease in areas where sporotrichosis is hyperendemic.[16] Pappas and colleagues described 238 cases that occurred in a remote region of the central highlands of Peru.[16] The incidence of disease ranged from 48 to 60 cases per 100,000 population and was highest among children 7 to 14 years of age, approaching 1 case per 1000. This report indicates that sporotrichosis in children is more common than is recognized, particularly in economically developing countries. Risk factors for sporotrichosis among children living in Peru included increased skin trauma (e.g., living in homes with dirt floors) and having contact with cats.

Clinical Manifestations

Most cases of sporotrichosis are localized to skin and lymphatic tissues. In contrast to sporotrichosis in adults, which can occur at any anatomic site, in children the disease most commonly affects the face and limbs, particularly the hands and fingers.[16–18]

Pulmonary and extrapulmonary infection occurs, including in joints, bones, the central nervous system, and other tissues, but it is less common. Systemic infection is more likely to occur in patients with altered host defenses, including people with diabetes, alcoholism, injection drug use, and other immunocompromising conditions, including those with AIDS. Systemic forms of sporotrichosis are rare in children.[16]

After inoculation the fungus replicates at the site of infection and then invades the regional lymphatics. In 25% of cases, infection remains confined to the initial site of inoculation, as it commonly does in facial lesions. Such “fixed” infections are more common in children than in adults.[5,19] Cutaneous sporotrichosis develops as a small, firm, painless papule or vesicle that initially is mobile but later becomes fixed. The lesion slowly enlarges over several weeks, and the skin and subcutaneous tissues surrounding the lesion become indurated and red. Within 10 days to 2 weeks after the appearance of the lesion, skin necrosis occurs, leaving a minimally painful superficial ulcer with irregular borders. In most cases the infection spreads to the regional lymph nodes that drain the site of the primary infection. The resulting ascending chain of nontender, mobile, subcutaneous nodules with overlying erythematous skin is the classic manifestation of sporotrichosis. Left untreated, the nodules enlarge slowly, soften, and can evolve into draining ulcers, even though the involved skin may not be painful (see Fig. 20.4).

In disseminated cutaneous sporotrichosis (which occurs in <1% of patients), numerous small papules or vesicles progress to necrotic, ulcerated nodules over the trunk and limbs. This form generally follows lymphatic or hematogenous spread from an initial cutaneous or pulmonary site of infection, but it also can be due to multiple cutaneous inoculations. The diagnosis of cutaneous or lymphocutaneous sporotrichosis should be suspected in any patient with papulovesicular or ulcerative lesions of the skin that are unresponsive to antibacterial treatment. Sporotrichosis should be suspected with the triad of painless skin ulcer, nodules along ascending lymphatics, and lack of response to antibacterial treatment. Other infectious etiologies that should be considered, in the appropriate epidemiologic setting, include blastomycosis, chromoblastomycosis, paracoccidioidomycosis, and leishmaniasis. “Fixed” cutaneous infections without lymphangitic spread are difficult to differentiate clinically from actinomycosis, nocardiosis, and nontuberculous mycobacterial disease.

Pulmonary sporotrichosis usually manifests as subacute or chronic pneumonia, which can be indistinguishable clinically from other chronic pulmonary infections. The symptoms, which are nonspecific, include a productive cough, fever, weight loss, anorexia, shortness of breath, and hemoptysis, which can be massive. Radiographic findings are nonspecific and can mimic tuberculosis parenchymal lesions, usually involving the upper lobes, which can cavitate. Hilar adenopathy and pleural involvement can occur. Disseminated sporotrichosis, which is uncommon in children, generally develops after lymphatic or hematogenous spread from an initial cutaneous infection or after pulmonary infection.[5] Skeletal involvement has been reported in up to 80% of patients with extracutaneous disease. A chronic destructive arthritis of the knee and other large weight-bearing joints is the most typical presentation, although the small joints of the hand and wrist can be involved. Meningitis is a rare but severe manifestation of disseminated sporotrichosis.

Diagnosis

Laboratory diagnosis of sporotrichosis can be difficult and depends on direct microscopy and culture of pathologic material. The results of direct microscopic examination can be negative because of the paucity of organisms in clinical samples (e.g., skin scrapings or exudates). Detection of the typical oval or cigar-shaped cells or asteroid bodies of *S. schenckii* complex in stained histologic sections confirms the diagnosis. Immunofluorescence is a sensitive and specific method but is not widely available for clinical use; molecular diagnostics methods also are undergoing evaluation.[20]

The diagnosis of sporotrichosis depends on isolation of the organism in culture from a specimen of soft tissue exudate or tissue biopsy. With visceral organ or osteoarticular infection, the yield is increased with cultures of tissue, rather than sputum, synovial, or other body fluids. Cultures incubated at room temperature usually are positive within a week.

Serology has not proved to be useful for the diagnosis of sporotrichosis, and tests that are not based on culture are not available.

Treatment

Guidelines for the treatment of sporotrichosis have been published.[21] Lymphocutaneous sporotrichosis uncommonly resolves without treatment.[13] Permanent scarring and disfigurement are common, as is bacterial superinfection. Oral itraconazole (in doses of 6 to 10 mg/kg/day, maximum 400 mg/day) is recommended for children with cutaneous or lymphocutaneous sporotrichosis, although lower doses (100 mg/day) also have been effective.[21,22] Therapy should be continued for 2 to 4 weeks after the lesions have resolved. In most patients, therapy is required for 3 to 6 months and is successful in more than 90%.[21,23] Fluconazole is less effective and should be regarded as a second-line agent for children who cannot tolerate other therapies or who do not absorb itraconazole.[21,24] Ketoconazole has less efficacy and more toxicity and should not be used. Data on the use of posaconazole or voriconazole for sporotrichosis are limited, but *Sporothrix* species frequently are resistant in vitro to voriconazole, which should not be used.[4,25] Oral terbinafine (up to 500 mg twice daily) has been effective for lymphocutaneous disease in small clinical studies in adults, but data in children are very limited.[26,27] Saturated solution of potassium iodide (SSKI) is the least costly option for lymphocutaneous infection and can be administered to children, but SSKI is associated with many side effects and thus is poorly tolerated by children and adults. Dose-limiting side effects include a strong metallic taste, gastrointestinal tract intolerance, salivary gland swelling, rash, and fever.[28] In children a dose of 50 mg or 1 drop 3 times daily in water or juice is given initially and increased as tolerated by 1 drop per dose per day (maximum of 1 drop/kg or 40 to 50 drops 3 times daily, whichever is *lower*).[21,29] Local application of heat, using a variety of warming devices or baths, has been reported as an effective alternative treatment for fixed cutaneous lesions but should be reserved for patients in whom antifungal drugs are contraindicated or not tolerated.[30]

For patients with life-threatening systemic or pulmonary sporotrichosis, amphotericin B (0.7 to 1 mg/kg/day) or liposomal amphotericin B (3 to 5 mg/kg/day) is recommended.[21] Itraconazole can be used for less seriously ill patients and as oral sequential therapy after an initial response to therapy with amphotericin B. Surgical resection, when possible, combined with antifungal therapy may improve outcome. Osteoarticular sporotrichosis usually is treated with itraconazole, which should be continued for 1 to 2 years.[21] Unfortunately, joint function uncommonly returns to normal. SSKI and terbinafine should not be used for osteoarticular sporotrichosis.[21]

Prevention

Sporotrichosis can be prevented by reducing skin trauma in high-risk settings (e.g., working with hay bales, moss, plants, rosebushes, and trees) by wearing protective clothing (e.g., long sleeves and gloves); by limiting animal exposures in specific epidemiologic settings (e.g., epidemic transmission from cats); or by avoiding exposure completely.[7,10,16]

Key Points

Diagnosis and Management of Sporotrichosis

Microbiology

- Thermally dimorphic fungus: grows as a mold in nature, with small budding yeast cells in tissue; grows within a week on routine microbiologic media

- Isolated in soil, decomposing vegetation: sphagnum moss, hay, rosebushes, wood

- Currently referred to as *Sporothrix schenckii* complex because of phylogenetic, phenotypic, and physiologic differences in strains; additional distinct species include *S. mexicana, S. globosa, S. luriei,* and *S. brasiliensis*

Epidemiology

- Occurs worldwide, most commonly as a cutaneous or lymphocutaneous infection

- Typically associated with minor trauma from thorns or wood splinters

- Zoonotic transmission: uncommon, usually from cats (which has led to current epidemic in Brazil and other regions globally); other animals (e.g., armadillos) also have been implicated

Clinical INFECTIONS

- Cutaneous or lymphocutaneous: especially common in children, including on the face and eyelids, perhaps as a result of autoinoculation

- Fixed lesion: painless papule with erythema and induration

- Lymphocutaneous lesion (more common): superficial ulcer with ascending lymphangitic chain of nontender, mobile, subcutaneous nodules or ulcers over erythematous skin

- Pulmonary infection: subacute or chronic pneumonia after inhalation of organism; nonspecific presentation, including productive cough, fever, weight loss, shortness of breath, and hemoptysis; nonspecific parenchymal infiltrates

- Disseminated infection: uncommon, especially in children; can involve bone and central nervous system

Diagnosis

- Recovery of organism in culture from body fluids or tissue specimens

- Microscopic examination of pathologic material can show oval or cigar-shaped cells or asteroid bodies.

- Immunofluorescent tissue stain is sensitive and specific but may not be available widely; molecular tools are in development.

Treatment

- Lymphocutaneous or cutaneous infection: itraconazole is the preferred therapy, usually for 3 to 6 months.

- Life-threatening disseminated or pulmonary infection: amphotericin B or liposomal amphotericin B, followed by itraconazole

- Osteoarticular or extrapulmonary infection: extended course of itraconazole

Cryptococcus Species

George R. Thompson III, Thomas F. Patterson

Most human cryptococcal infections are caused by one of two species, *Cryptococcus neoformans* or *C. gattii*.[1,2] These species previously were divided into three entities, *C. neoformans* var. *neoformans*, *C. neoformans* var. *grubii*, and *C. neoformans* var. *gattii*, which were classified into eight molecular genotypes and five serotypes based on capsular polysaccharide antigens. Serotypes A and D and the hybrid diploid AD strains belong to *C. neoformans;* serotypes B and C strains are classified as *C. gattii* (Table 249.1). Currently serotype A strains are designated *C. neoformans* var. *grubii*, and serotype D strains are designated *C. neoformans* var. *neoformans*, although these may soon be given species designation.[3–6] *C. neoformans* var. *grubii* has a worldwide distribution and is the most common causative agent of cryptococcosis in people with acquired immunodeficiency syndrome (AIDS) and other immunocompromised people, accounting for more than 95% of cases of cryptococcal infection.[4,7] In contrast, *C. gattii* usually affects immunocompetent people living in the tropics and subtropics. It has been associated with eucalyptus trees, which were considered its major environmental niche. As reported in 2004, *C. gattii* caused a substantial outbreak of cryptococcal infections on Vancouver Island, British Columbia, expanding its geographic boundaries and demonstrating its association with other trees as well.[8]

Several factors contribute to the virulence of *C. neoformans*, including the ability to grow in the environment and at 37°C, production of a polysaccharide capsule, and the ability to produce melanin. Acapsular strains of *Cryptococcus* exhibit a marked decrease in virulence. The ability to produce melanin is thought to play a role in both the virulence and the neurotropism of *C. neoformans* because melanin-deficient mutants are less virulent in mice, and the central nervous system (CNS) is rich in precursors for the production of melanin.[9] Primary infection with cryptococci usually occurs after the organism is inhaled into the lungs. Cryptococci are controlled principally by cell-mediated immunity in conjunction with phagocytosis.[10] Initially, neutrophils play a role in containing the yeast in the lungs, followed by monocyte activity. $CD4^+$ T lymphocytes have been shown to be essential in containing CNS infection, which may account for the much higher incidence of cryptococcosis in people with AIDS. Although antibody and complement cannot kill cryptococci directly, both enhance opsonization.[7]

Epidemiology

C. neoformans and *C. gattii* differ in their natural habitat and geographic distribution. *C. gattii* causes infection in tropical and subtropical regions of the world and is associated with several species of eucalyptus trees, which are its ecologic niche. However, the outbreak of *C. gattii* infections on Vancouver Island demonstrated an association with other trees, including firs and oaks, and an expanded geographic range.[8] For *C. neoformans*, both *C. neoformans* var. *grubii* (serotype A) and *C. neoformans* var. *neoformans* (serotype D) are isolated most frequently from soil contaminated with pigeon or other bird guano.[11] The two varieties differ in their geographic distribution; serotype A has been isolated throughout the world and usually infects people with AIDS or other immunocompromising conditions, whereas serotype D infections are more prevalent in certain geographic areas, such as northern Europe.[7]

Although *Cryptococcus* species can be isolated from pigeon droppings, documentation of infection after this type of exposure is limited.[12] Molecular strain typing has not yet linked a specific environmental source to cryptococcosis, but it has demonstrated that some clinical and environmental isolates are indistinguishable.[13] Host factors are important in determining the risk of developing cryptococcosis. HIV infection is now the most common immunocompromising illness in patients with cryptococcosis, although the incidence of cryptococcosis has decreased with the institution of active antiretroviral therapy (ART). However, in areas worldwide where ART is not available, cryptococcosis remains the most common life-threatening fungal infection.[7] In people with HIV infection, cryptococcosis usually occurs in patients with CD4$^+$ lymphocyte counts below 100 cells/mm^3.[14] Other immunocompromised people with cell-mediated immunologic defects, such as patients with lymphoma and sarcoidosis, and people receiving corticosteroid treatment, also have an increased risk of both *C. neoformans* and *C. gattii* infections.[15] No association between cryptococcosis and ethnicity has been detected.[14]

Until the AIDS epidemic began, cryptococcosis was rare. Population-based active surveillance conducted in four areas of the United States between 1992 and 1994 showed that cryptococcosis developed in 2% to 5% of people with AIDS per year.[14] The rate of cryptococcal infection in HIV-infected people declined dramatically after the introduction of ART; it decreased by 46% in one study, and in another study dropped from an incidence as high as 66 per 1000 to 2 to 7 per 1000.[16,17] Also noteworthy is the fact that of the 1083 cases of cryptococcosis detected during a population-based surveillance study before ART, only 4 cases occurred in people younger than 18 years of age, 2 of whom were infected with HIV.[14] These data were confirmed by other studies showing that cryptococcal infection was less common in HIV-infected children than in HIV-infected adults, with occurrence rates of 1% and 1.4%, respectively.[18,19] Most pediatric cases of cryptococcosis occurred in children 6 to 12 years of age; 9 of 13 cases diagnosed after 1990 occurred in children with vertical HIV infection. Similarly *C. gattii* infection is uncommon in children; only three confirmed cases have been reported (all pulmonary and all in patients who were not infected with HIV).[20]

Occasional cases of cryptococcosis occur in children without HIV infection, the most common underlying conditions being lymphoproliferative disorders and immunosuppressive treatment.[21] Rare cases occur in apparently healthy children. The reasons for the lower incidence reported in children is unknown but may relate to differences in environmental exposures or immunologic factors.

Clinical Manifestations

Cryptococcosis is acquired by inhalation of infectious airborne particles. The incubation period is unknown and could be weeks, months, or even longer. Whether the infectious particles are desiccated acapsular yeast cells or basidiospores of the sexual state of the fungus is unclear, but the encapsulated yeast cells are thought to be too large to penetrate the defenses of the upper respiratory tract. After inhalation organisms disseminate in immunocompromised patients from the lungs to other sites, with or without evident pulmonary infection. Any organ can be affected, including bone and soft tissue, but the most serious form of the disease is meningitis or meningoencephalitis, which is fatal if untreated.[7]

The clinical manifestations of cryptococcosis in children with AIDS are similar to those in HIV-infected adults.[18,19,21] The presentation of cryptococcosis in patients with AIDS more commonly involves extrapulmonary disease, including cryptococcemia, and extensive CNS infection with a high burden of organisms, as manifested by positive results on India ink examinations and antigen titers, in addition to a limited cerebrospinal fluid (CSF) inflammatory response.[22]

Pulmonary Manifestations

Primary cryptococcosis is asymptomatic in up to one third of immunocompetent people after inhalation of *C. neoformans*.[23] Even in immunocompromised patients, including people with AIDS, primary pulmonary infection may not be diagnosed until extrapulmonary dissemination occurs, particularly meningitis.[24] More persistent pulmonary cryptococcosis often develops in people with HIV infection. Most patients come to medical attention with headache, fever, cough, dyspnea, and weight loss, and some have pleuritic chest pain and hemoptysis. The most frequent radiographic findings are focal or diffuse interstitial infiltrates and hilar lymphadenopathy. Unlike in patients with filamentous fungal infections, nodular and alveolar infiltrates are rare, as are large mass lesions and pleural effusions.[23,25]

Neurologic Manifestations

Infection of the CNS is the most common clinical presentation of cryptococcosis and the complication most frequently associated with mortality. Although cryptococcal meningitis can be acute, it most often follows an indolent course, with asymptomatic periods. In people with AIDS, the most common symptoms are headache, fever, and altered mental status; meningeal signs are uncommon. Focal neurologic signs are initially uncommon and occur in about 10% of patients. If focal lesions are detected, especially in patients with AIDS, another diagnosis, such as brain abscess arising from another infectious cause (e.g., toxoplasmosis, tuberculosis, bacterial abscess) or malignancy (primary CNS lymphoma) should be considered because CNS mass lesions (cryptococcomas) have not been reported in HIV-infected children.[26] Increased intracranial pressure is common in patients with CNS cryptococcosis, especially those with AIDS, and represents a life-threatening complication. These patients present with severe headache, abnormal mental status, visual disturbance, and frequently hearing loss.[27,28] The underlying mechanism is unclear, but it is thought to be partly the result of interference with CSF reabsorption in the arachnoid villi due to accumulation of fungal polysaccharide. Aggressive management of elevated intracranial pressure by means of repeated lumbar CSF drainage is perhaps the most important factor in reducing mortality and minimizing the morbidity of acute cryptococcal meningitis.[27]

About 90% of patients with cryptococcal meningitis who are not infected with HIV have abnormal CSF findings, including increased opening pressure (65%), elevated protein concentration (90%), lowered glucose concentration (75%), and a lymphocytic pleocytosis. In people with AIDS, the CSF can appear normal, having normal protein and glucose concentrations and minimal or absent pleocytosis.[29]

Skin Manifestations

Cryptococcal skin lesions occur in 10% to 15% of patients with disseminated disease as a result of hematogenous spread. Direct extension from a bone lesion can also occur. Single or multiple pustules or papules are most common and sometimes progress to ulcers or abscesses. These lesions typically are described as resembling molluscum contagiosum, and without a biopsy and culture they cannot be distinguished from lesions caused by other infectious agents, such as *Histoplasma capsulatum, Coccidioides immitis,* and *Talaromyces* (formerly *Penicillium*) *marneffei.*[30] Although the most common sites of cryptococcal skin lesions are the face and scalp, the trunk or limbs also can be involved.

Other Sites

Bone infection occurs in about 5% to 10% of patients with disseminated cryptococcosis. Pain and swelling can be present, but bone lesions often are found incidentally. Radiographs reveal well-defined osteolytic lesions without marginal sclerosis or periosteal change. Joint involvement is rare. Eye involvement with cryptococcal meningitis can occur and manifests as retinitis. Cryptococcosis can involve any organ system, including the adrenal glands, heart, liver, spleen, and prostate.

Diagnosis

Diagnosis is not usually difficult; it requires isolation of *Cryptococcus* organisms in culture or detection of cryptococcal capsular antigen in the blood, CSF, or urine.

Encapsulated *C. neoformans* often can be seen on direct microscopic examination of CSF or other body fluids and secretions mounted in India ink, mucicarmine, or other stains, such as nigrosin. In people with AIDS, *C. neoformans* cells usually are plentiful in the CSF, although care must be taken not to confuse organisms with lymphocytes in CSF. Budding of the organism can be useful for that distinction.

C. neoformans can be isolated from CSF in 75% to 90% of cases of cryptococcal meningitis, and a culture is even more likely to be positive in patients with AIDS because of the high burden of organisms.[29] In patients with negative cultures, periodic high-volume CSF samples (>10 mL) may increase the yield. The organism grows well on standard microbiologic media and fungal media (e.g., Sabouraud dextrose agar), but it is inhibited in media containing cycloheximide. *C. gattii* grows as deep blue colonies on a canavanine-glycine-bromothymol (CGB) culture medium, but *C. neoformans* does not induce a color change on this medium (Fig. 249.1). Growth is enhanced at 30°C to 35°C, and incubation should be extended for up to 2 weeks in suspected cases. Blood and urine cultures also can be positive. Isolation of *Cryptococcus* organisms from respiratory tract samples, including sputum, bronchoalveolar lavage fluid, or lung tissue, may be useful in pulmonary infection. Immunocompromised patients with pulmonary cryptococcosis should be evaluated for CNS disease.

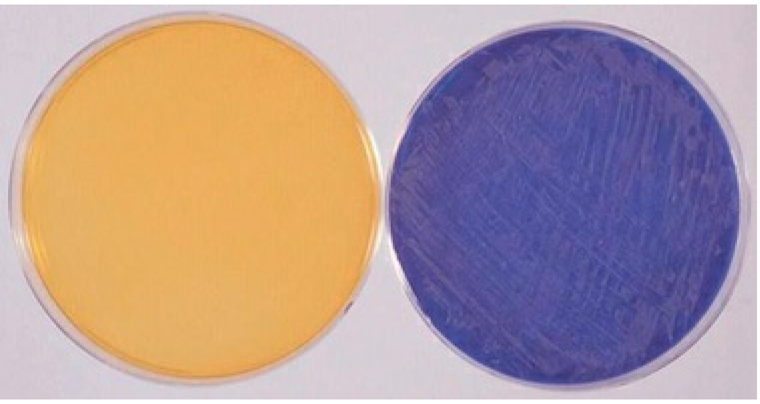

FIGURE 249.1 *Cryptococcus gattii* causes a cobalt blue color change when grown on canavanine-glycine-bromothymol (CGB) culture media *(right)*, whereas *C. neoformans* does not *(left).*

Testing for cryptococcal capsular antigen in serum, CSF, urine, or bronchoalveolar lavage specimens is one of the most reliable nonculture methods of fungal diagnosis. The antigen test is positive in more than 90% of patients with untreated cryptococcal meningitis, but it is somewhat less sensitive in patients without CNS disease. The test is highly specific, and false-positive results are seen primarily in other basidiomycetous yeast infections, such as those caused by *Trichosporon* spp. False-negative test results can occur if the organism burden is low or if the organisms are not well encapsulated. Tests to detect serum antibodies to *C. neoformans* have been less helpful because such antibodies are seldom found in patients with untreated meningeal or disseminated infection, although their presence may indicate a favorable prognosis.[31]

Antigen tests should be performed on all CSF specimens at the time of initial diagnosis, and the results can be measured on subsequent CSF specimens to evaluate the response to treatment, although serial CSF antigen titers have a limited role in management.[32] Serum antigen levels are even less useful for monitoring the response to treatment, likely because of the persistence of polysaccharide capsules. Various commercial tests are available for detection of cryptococcal antigen, and these now use the enzyme immunoassay rather than the original latex agglutination assay.

Treatment

Left untreated, cryptococcal meningitis is fatal.[33] Because treatment for cryptococcal disease has not been studied in a controlled manner in pediatric patients, data from adult trials have been used to formulate recommendations for treating cryptococcal infection in children.[34,35] For most patients with severe cryptococcosis and cryptococcal meningitis, combination therapy with amphotericin B and flucytosine for 2 weeks, then 8 weeks of therapy with fluconazole, is recommended.[35,36] This approach is associated with a mortality rate of less than 10% and a mycologic response greater than 70%.[34,37]

Amphotericin B deoxycholate remains the standard agent for treating other serious cryptococcal infections, even though it must be administered parenterally and is associated with dose-limiting toxicities.[36] Amphotericin B usually is given at a dose of 0.7 to 1 mg/kg/day in combination with flucytosine at 100 mg/kg/day, in 4 divided doses for 2 weeks, followed by therapy with fluconazole or itraconazole for 8 weeks or until cultures are sterile.[35,36] Lipid-based formulations of amphotericin B reduce the toxicities of this drug. Although the optimal doses of these agents have not been established, a dose of 3 to 5 mg/kg/day has been effective.[38,39] Cost remains a serious obstacle to their routine use.

Flucytosine is an orally bioavailable antifungal agent with potent activity against *C. neoformans,* but resistance develops rapidly when the drug is used as a single agent. When flucytosine is given in combination with amphotericin B, relapses are reduced and cultures become negative more quickly[37]; more recent studies have shown a survival benefit to this approach.[40] Flucytosine has the potential for considerable toxicities, including bone marrow suppression, nausea and vomiting, and skin and kidney toxicities, especially in patients with abnormal renal function.

The triazole antifungal agents, including fluconazole and itraconazole, and the extended spectrum triazoles, voriconazole and posaconazole, have excellent activity against *C. neoformans.*[41] Because fluconazole crosses the blood-brain barrier, achieves good CSF concentrations, and is well tolerated, it has become the primary azole used in cryptococcal meningitis. For children with mild to moderate cryptococcosis that does not involve the CNS or that is confined to the lungs, fluconazole alone can be considered for primary therapy. However, higher failure and mortality rates are associated with the use of fluconazole as the primary therapy of cryptococcal meningitis; therefore, use of this drug as a single agent is not recommended in most patients with more severe infection or meningitis.[36]

For children with cryptococcal meningitis who are completing a 2-week induction course of amphotericin B combined with flucytosine, fluconazole (10 to 12 mg/kg/day divided into 2 doses daily, given either intravenously or orally) then is recommended for a minimum of 8 weeks.[35] Itraconazole is an alternative, but it does not penetrate well into the CSF, and it is associated with significant drug interactions and gastrointestinal tract intolerance.[35]

Refractory infection can occur and usually is related to the severe immunocompromised condition of the person, more than to antifungal resistance, which is uncommon.[41] Susceptibility testing of *Cryptococcus* organisms has limited clinical value. Clinically the more important course is to confirm the diagnosis and to establish drug compliance and lack of interactions that limit drug exposure. Alternative agents are available, including voriconazole and posaconazole, both of which have been shown in anecdotal series to have activity, although overall responses are not favorable because of their use almost exclusively as late salvage therapy in very immunosuppressed patients.[42,43] The echinocandins do not have activity against *Cryptococcus* species because of a difference in the fungal cell wall; therefore, these drugs should not be used.[44]

Prevention of relapse after successful treatment requires long-term suppressive treatment.[35] After 10 weeks the dosage of fluconazole can be reduced to an adolescent or adult dose of 200 mg/day, depending on the patient's clinical status. The safety of discontinuing secondary prophylaxis in children infected with HIV after immune reconstitution with ART has not been studied extensively, but cases in adults and adolescents appear to indicate that the risk of relapse is low once the $CD4^+$ lymphocyte count has risen above 200 cells/mm^3.[34] Suppressive therapy should be reinstated if later the $CD4^+$ lymphocyte count drops below 200 cells/mm.[3]

Special Management Considerations

In all cases of cryptococcal meningitis careful attention to the management of intracranial pressure is essential to ensure an optimal clinical outcome.[27,28] The principal intervention for reducing elevated intracranial pressure is percutaneous lumbar drainage of CSF. Radiographic imaging of the brain is recommended before the initial lumbar puncture to rule out a space-occupying lesion.[36] Enough CSF should be removed to reduce the opening pressure by 50%. If repeated lumbar punctures or use of a lumbar drain fails to control the symptoms of elevated pressure, or when persistent or progressive neurologic deficits are present, a ventriculoperitoneal shunt is indicated.[36] Adjunctive treatment with corticosteroid therapy is not recommended in patients with HIV infection.[36] Also, the use of acetazolamide therapy is associated with increased toxicity, including severe acidosis in one trial in adults, and is not recommended.[45]

ART has significantly improved the long-term outcomes associated with cryptococcal infection in patients infected with HIV and has reduced the incidence of disease. However, in the past decade an immune reconstitution inflammatory syndrome (IRIS) has been reported after initiation of ART in the acute treatment phase of opportunistic diseases in both adults and children.[46,47] Symptoms include elevated intracranial pressure, CSF pleocytosis, fever, headache, and meningismus, which can make it difficult to distinguish IRIS from relapse or progression of disease.[48,49] IRIS (which also can occur in patients without HIV infection who have a rapidly recovering immune system, such as after stopping immunosuppressive therapy) generally occurs within the first 1 to 2 months after the start of ART; for this reason, delaying ART until the patient has completed 5 weeks of antifungal therapy for cryptococcal infection should be considered. This approach is associated with a survival benefit.[50]

Prevention

Guidelines have been published for the prevention of opportunistic infections, including cryptococcosis, in people with HIV infection.[51] Several studies have demonstrated that prophylactic administration of fluconazole to people with HIV infection who are at high risk for cryptococcosis can significantly reduce the risk of development of the disease.[52,53] In selected countries with limited resources, screening of asymptomatic patients for serum cryptococcal antigen is recommended.[54] However, the use of fluconazole to prevent cryptococcal infection in the U.S. is not recommended because of the relative infrequency of infection and the unfavorable cost-benefit ratio of this approach.[55] No vaccine is available.

Key Points

Diagnosis and Management of Cryptococcal Infections

Microbiology

- Encapsulated, basidiomycetous yeasts; grow well on routine microbiologic media
- Two species (*C. neoformans* and *C. gattii*) account for most of invasive infections.
- *C. gattii* grows as deep blue colonies on canavanine-glycine-bromothymol blue media, whereas *C. neoformans* is unable to induce a color change on this media.

Epidemiology

- Occurs worldwide but only rarely causes disseminated infection in immunocompetent people
- Estimated 1 million cases in adults and children worldwide per year, and 700,000 deaths
- Major risk factors: AIDS, prolonged glucocorticoid treatment, organ transplantation, hematologic malignancy, sarcoidosis, or use of other immunosuppressive medications
- Cryptococcosis is uncommon in children (even those with AIDS) compared with adults, for unknown reasons.

Clinical Features

- Central nervous system: often indolent, with headache, fever, and altered mental status most common; focal neurologic deficits present in 10%; increased intracranial pressure very common

- Pulmonary: cough, pleuritic chest pain, hemoptysis, and focal or diffuse interstitial infiltrates with hilar lymphadenopathy
- Cutaneous: typically seen in those with disseminated disease; can mimic molluscum contagiosum
- Other: any organ system can be affected, including adrenals, heart, liver, spleen, and prostate

Diagnosis

- Recovery of organism from body fluids or tissue
- Microscopic examination of cerebrospinal fluid (CSF) on wet mounts stained with India ink
- Detection of cryptococcal capsular antigen in blood, CSF, or urine

Treatment

- CNS: combination amphotericin B and flucytosine for 2 weeks, then fluconazole for 8 weeks. Fluconazole should be continued until immune reconstitution is observed (CD4$^+$ lymphocyte count >200 cells/mm^3 for at least 6 months)
- CNS: attention to intracranial pressure and attempt to reduce urgently if elevated
- Immune reconstitution inflammatory syndrome (IRIS): can occur after recovery of immunologic responsiveness; complicates management

Histoplasma capsulatum (Histoplasmosis)

John C. Christenson, Martin B. Kleiman

Histoplasmosis is the most common primary systemic mycosis in the Americas, affecting hundred of thousands of people living in urban and rural areas of the Ohio and Mississippi River valleys and some mideastern states, and parts of Central and South America.[1,2] The fungus is also endemic to Australia, Africa, and eastern Asia.[3–5]

The Pathogen

Microbiology

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum* var. *capsulatum*. Another variant, *H. capsulatum* var. *duboisii*, is known to cause disease in Africa. A common soil saprophyte, *H. capsulatum* grows as a spore-bearing mold below 35°C and as a yeast-like organism at 37°C. In its mold form, tuberculate macroconidia 8 to 14 μm in diameter are an identifying morphologic feature (Fig. 250.1A). Morphologic methods of identifying *H. capsulatum* isolates are slow, laborious, and hazardous; DNA probe technology shortens the time required for identification.[6] The infectious particles are the microconidia, spores

2 to 5 μm in diameter that are produced by the mold form. Yeast-like forms are 2 to 3 μm by 3 to 4 μm in diameter and typically are found in infected tissues (Fig. 250.1B and C).

Pathogenesis

After inhalation, microconidia germinate within distal bronchioles and pulmonary alveoli, where they undergo transition to yeast-like forms. Acute inflammatory changes ensue. Lymphohematogenous fungal dissemination occurs early in infection, even in self-limited disease.[7] The successful pathogenesis of *H. capsulatum* results from the organism's transition to the yeast phase, entry into and proliferation within macrophages, and ability to survive and retain its ability to reactivate.[8–12] In healthy people, specific T-lymphocyte immunity develops after 1 month and interleukin-12 (IL-12) and interferon γ (IFNγ) stimulate macrophages to kill the fungus, thereby controlling disease. Tumor necrosis factor-α (TNF-α) is also critical for effective host immunity.[13] Histopathologic changes include granulomas with Langerhans giant cells, typical yeast-like forms, and caseous necrosis.[14] Lesions heal by fibrous encapsulation and can calcify. In some patients, albeit rarely in children, an exuberant fibrous reaction destroys or obstructs major vessels, bronchi, or lung parenchyma, and/or critical mediastinal structures. In immunocompromised people or those with progressive disseminated infection, granulomas can be poorly formed and the large fungal burden can overwhelm the reticuloendothelial system.[15,16] Findings compatible with macrophage activation syndrome can occur in this setting.[17]

Immunity

Antibodies against the organism are measurable about 1 month after infection, but these play no major role in controlling infection. In healthy people the cell-mediated immune response is the key to controlling fungal growth and provides a degree of protection against reinfection.[18] *H. capsulatum* replicates within macrophages until T lymphocytes are activated.[13] Granuloma formation occurs in response to infection of macrophages.[19] The release of proinflammatory cytokines and chemokines is required for the development of a protective immune response that not only controls the infection, but also provides protection against recurrent infection.[20] Reinfection usually results from reexposure; recurrences have shorter incubation periods and are generally milder than primary infections. Recrudescence of latent infection has been well documented in people infected with HIV,[21] in recipients of organs transplanted from infected donors,[22] and in people receiving corticosteroids[23] or TNF-α inhibitors[13,24–27]; however, the frequency of reactivation, versus reexposure-induced infection, is the subject of debate. Progressive disseminated infections that occur in otherwise immunocompetent people, especially infants, can cause a transient T-lymphocyte deficiency that resolves after eradication of the organism.[15,16]

Epidemiology

Areas of high incidence include the Mississippi and Ohio River valleys (Fig. 250.2), where skin test reactivity in hyperendemic areas can develop in as many as 80% of people by 18 years of age.[2,28] Infections can occur sporadically or in clusters.[29–34] A single epidemic of more than 100,000 cases of infection has been described in Indianapolis.[1] Bird and bat excrement promote fungal growth in the environment. Inhalation of aerosols generated when contaminated areas are disturbed are risk factors for infection. Box 250.1 presents a summary of activities and point sources that most often predispose to infection. Contaminated air in closed spaces can cause intense exposure and serious illness. Large outbreaks have been reported in industrial settings and in a school.[30,33,34] Infections increasingly are reported among travelers returning from endemic areas.[31,35–41] Vertically acquired, disseminated histoplasmosis and HIV infection have been reported in a 5-week-old infant.[42]

Clinical Manifestations

In settings other than outbreaks, symptomatic infection occurs in less than 5% of infected individuals, and clinical manifestations vary widely. The outcome of exposure to *H. capsulatum* is influenced by (1) inoculum size; (2) the functional integrity of the person's cellular immunity; (3) strain-specific virulence factors; and (4) preexisting immunity.

Immunocompetent People

The spectrum of common clinical manifestations of histoplasmosis in childhood is summarized in Box 250.2. In a single-source, high-inoculum outbreak at a high school, 523 people developed serologic evidence of recent infection, and 355 (68%) developed symptoms compatible with acute pulmonary histoplasmosis.[30] Most became symptomatic 2 to 3 weeks after exposure. Common complaints were headache (95%), fatigue (79%), fever (79%), cough (73%), myalgias (71%), chills (67%), nonpleuritic chest pain (66%), and arthralgias (52%).

Symptoms of histoplasmosis in children usually last 2 or 3 days. In about 5% of children, symptoms are subacute, persist longer than 2 weeks, and include lethargy, poor appetite, and weight loss. Rheumatologic manifestations can occur, including erythema nodosum (Fig. 250.3), arthralgia, or both, often in adolescents.[41] In about 10% of symptomatic children, pericardial effusion develops and, albeit infrequently, can become large enough to impair diastolic filling.[43,44] Pericardial fluid is almost always sterile and usually results from inflammation caused by infected contiguous lymph nodes. Hypercalcemia, occasionally seen with other granulomatous infections, can occur in histoplasmosis.[45] Many mediastinal and abdominal manifestations result from irritation, compression, or destruction of structures adjacent to infected lymph nodes and granulomas.[46,47] Other manifestations include chylothorax,[48] pleural effusion,[49,50] multifocal choroiditis,[51] cystic duct obstruction,[52] and traction esophageal diverticulum.[53] Osteomyelitis[54] and central nervous system infections[55,56] are unusual manifestations of histoplasmosis in healthy older children. Except in cases of massive exposure, fatality is rare in otherwise healthy older children.

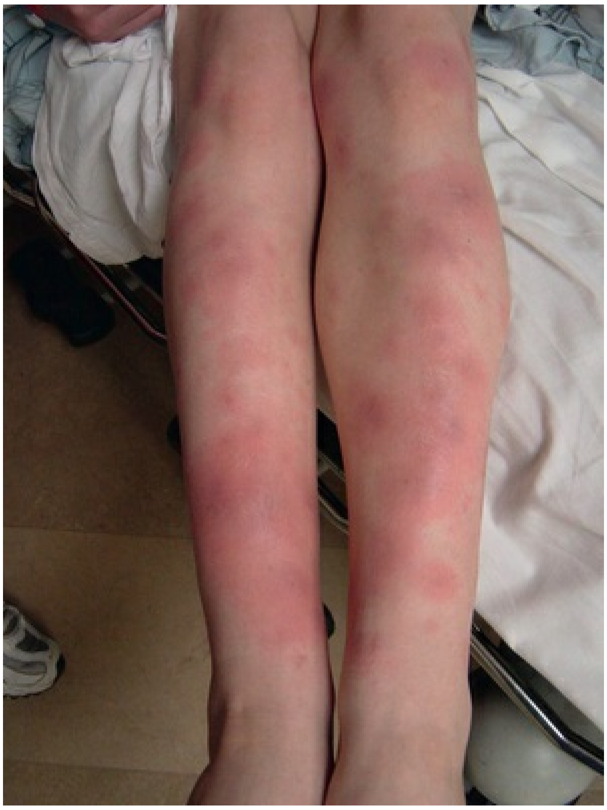

FIGURE 250.3 Erythema nodosum in an adolescent male with acute pulmonary histoplasmosis.

Fungal dissemination that occurs early in infection almost always is self-limited in healthy people. The term *progressive disseminated histoplasmosis* is applied to instances of continued and overwhelming reticuloendothelial infection, which is fatal if left untreated.[16,46] This manifestation often suppresses cellular immune function in previously immunocompetent people, and it is a common opportunistic infection in individuals with acquired or congenital cellular immune dysfunction.[15] An infrequent manifestation of progressive dissemination occurs in otherwise healthy infants. Termed *progressive disseminated histoplasmosis of infancy*, its initial symptoms are subacute, sometimes lasting several weeks, although progressive.[16,46] Complaints and signs include fever, weight loss, and progressive hepatosplenomegaly (Fig. 250.4). Meningitis occurs in about 60% of affected infants. Pancytopenia and disseminated intravascular coagulation (DIC) are ominous signs; the infection is fatal if it goes untreated. Interestingly, a recent report describes a case of disseminated histoplasmosis in one of infant twins.[57]

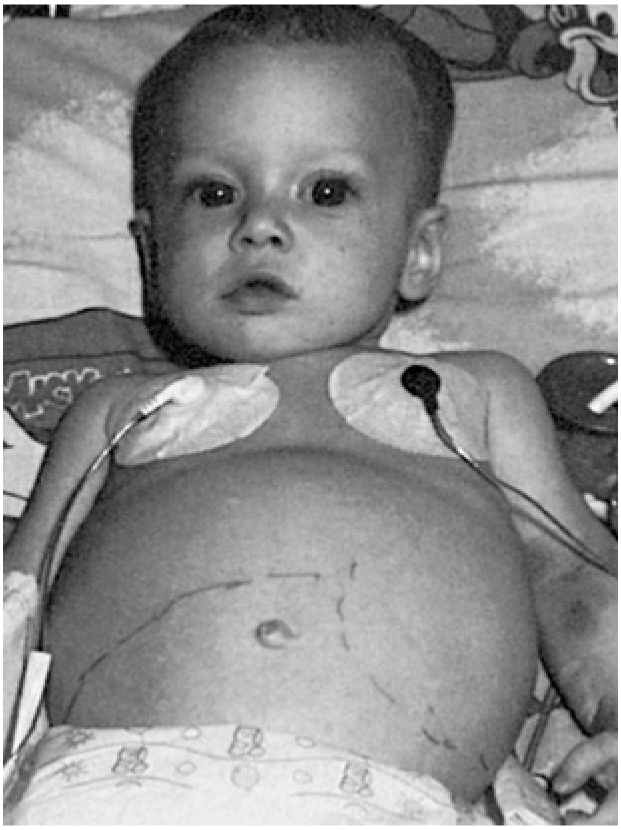

FIGURE 250.4 Six-month-old boy with disseminated histoplasmosis. He had a 1-month history of failing to thrive and a “swollen abdomen.” Note the characteristic appearance with massive hepatosplenomegaly and early signs of cachexia, yet the baby has a bright, responsive facial appearance.

Immunocompromised People

Impaired cellular immunity markedly increases the risk of progressive dissemination and life-threatening infection.[21,58–60] In addition to immunosuppressive therapy for malignancies or transplantation,[22,61,62] increased risk has been associated with the use of TNF antagonists used to treat inflammatory conditions.[24–27] Illness usually begins with fever, and then cough, diffuse pulmonary infiltrates and, ultimately, hypoxia occur. Patients with HIV infection may have only a prolonged fever and weight loss, and no pulmonary findings.[63,64] Occasionally, large necrotic masses of infected lymph nodes can develop. Data for children are lacking; however, in adults with HIV infection complicated by histoplasmosis, multiorgan dysfunction, DIC, elevated serum levels of lactic dehydrogenase, shock, and respiratory failure are predictive of death.[64] In patients receiving combination antiretroviral therapy (cART), immune reconstitution can cause recurrence of symptoms to develop.[65,66]

Laboratory Findings and Diagnosis

Nonspecific Tests

In self-limited histoplasmosis in an immunocompetent person, a hemogram may show only mild anemia. The erythrocyte sedimentation rate almost always is elevated. Pancytopenia and DIC often are seen in untreated, progressive disseminated histoplasmosis. Hemophagocytosis can occur in disseminated infections in immunocompromised people.[67] For an immunocompetent person with histoplasmosis, histopathologic examination shows well-formed, necrotizing, granulomatous inflammation. In immunocompromised patients, the histologic findings are poorly formed granulomas with sheets of histiocytes containing typical yeasts.[19,68]

A chest radiograph in a person with an acute infection can be normal, or it can show a middle mediastinal mass and lymphadenopathy, or localized pulmonary infiltrates, or both (Fig. 250.5).[69] Some clinical, laboratory, and imaging findings help distinguish a benign mediastinal mass (e.g., caused by histoplasmosis) from a malignancy.[69a] CT of the chest is more sensitive than plain radiography (Fig. 250.6). In a high-inoculum exposure or in immunocompromised people, a diffuse reticulonodular infiltrate can be observed (Fig. 250.7). Radiographs or CT scans of asymptomatic residents of endemic regions often reveal single or multiple calcified nodules in the lungs and hilar lymph nodes and, occasionally, calcifications in the spleen or liver (Fig. 250.8). These findings usually are the result of previous, often unrecognized infections.

Specific Laboratory Tests

The principal laboratory tests for diagnosis of histoplasmosis are serologic tests, culture, and tissue and body fluid examinations, along with quantitative enzyme immunoassay (EIA) for *Histoplasma* antigen in the urine, serum, cerebrospinal fluid, and bronchoalveolar lavage fluid.[70–74] Table 250.1 provides an interpretive guide to laboratory test results in children with histoplasmosis. Multiple positive test results, especially in children with clinically compatible illnesses, increase the positive predictive value of marginally positive serologic results.

Immunodiffusion and complement fixation assays that detect *Histoplasma*-specific antibody are positive in about 90% of infections in immunocompetent patients.[70] The titer of antibody by the complement fixation test is directly proportional to the severity of the illness and the degree of exposure.[30,75] In acute, self-limited infections, measurable antibody appears 4 to 6 weeks after infection and can revert to negative after 12 to 18 months. Although more sensitive than the immunodiffusion test, the complement fixation test is less specific, showing 18% cross-reactivity with antigens of *Blastomyces, Paracoccidioides,* and *Coccidioides,* in addition to other fungi.[76] The clinical features, exposure and travel histories, and results of other diagnostic tests aid in differentiating these entities. In the immunodiffusion precipitin test, H bands are found in only 23% of patients with an acute pulmonary infection but are more highly suggestive of active infection than are M bands; M bands are found in 76%. The immunodiffusion assay is quite specific, showing cross-reactions in only 5%.

A positive culture is confirmatory, but growth may take up to 6 weeks. The sensitivity of culture is low in all but severe, progressive dissemination and chronic pulmonary infection. The organism can be isolated in blood from patients with disseminated disease by using lysis centrifugation blood culture methods.[77] In the presence of a compatible illness and the probability of exposure, observation by an experienced examiner of yeast-like forms compatible with *H. capsulatum* in tissue, bone marrow, bronchoalveolar lavage fluid, or peripheral blood often is diagnostic (see Fig. 250.1B and C). Exceptions can include instances in which typical, though nonviable, organisms are observed within granulomas in patients with past infections.[78] Although progress has been made in molecular methodology that can detect *H. capsulatum* in tissue specimens, assays are not commercially available.[79–81]

A rapid EIA that quantifies *Histoplasma* antigen in urine, serum, bronchoalveolar lavage, and cerebrospinal fluid is available for diagnosis.[74,82–85] The EIA demonstrates high sensitivity in serious manifestations of infection, including early primary pulmonary infection and serious and life-threatening histoplasmosis. EIA is especially useful for immunocompromised patients in whom serologic tests can be falsely negative. In a highly endemic region, antigenuria was detected in 100% of children with progressive, disseminated histoplasmosis. Because the assay reflects the fungal burden, it also is used both to monitor the effectiveness of treatment and thereafter to detect relapse.[57] Serum specimens (in which simultaneously measured concentrations are substantially lower than those of urine) should be used to monitor the effectiveness of treatment in individuals whose urine concentrations are very high. When antigen becomes undetectable in the serum, urine specimens can be used for follow-up. After therapy is completed, EIA on urine samples can be used to detect early relapse in individuals at high risk for recurrence.[72,73] Although reasonably specific, the *Histoplasma* antigen assay can cross-react with *P. brasiliensis, B. dermatitidis, C. immitis* and *C. posadasii,* and *Penicillium marneffei.*[85] However, differentiation of these endemic mycoses usually is straightforward when clinical manifestations, serologic tests, and geographic considerations are evaluated. Low-positive *Histoplasma* urine antigen results (<0.6 ng/mL) must be interpreted with caution. Although they may represent histoplasmosis infection, they also can indicate cross-reaction with another fungal antigen.[86–88] False-positive results occur in 1% of specimens.

Differential Diagnosis

The differential diagnosis of symptomatic pulmonary histoplasmosis usually includes tuberculosis, with which clinical and radiographic findings often overlap. Other subacute infections that cause similar findings include blastomycosis and coccidioidomycosis. When middle mediastinal/hilar lymphadenopathy is disproportionate to the degree of pulmonary infiltrates, histoplasmosis can mimic lymphoma, particularly in patients with fever and weight loss. In a series of patients residing in an endemic area, all children with middle mediastinal adenopathy and complement fixation titers of 1 : 32 or higher were diagnosed accurately with histoplasmosis.[69] Progressive disseminated forms of histoplasmosis can mimic septicemia, leukemia, or a reticuloendothelial or primary gastrointestinal tract neoplasm, if the initial signs include hepatosplenomegaly, anemia, thrombocytopenia, leukopenia, coagulopathy, hemorrhage from gastrointestinal ulceration, or any combination of these conditions.[59,89]

Because severe, disseminated, or recurrent histoplasmosis can represent an opportunistic infection, evaluation should include screening for a previously unrecognized acquired or congenital immunodeficiency disorder.[65,66,90,91]

Treatment

Key factors used to determine whether antifungal therapy for histoplasmosis is needed are the clinical manifestations, severity of symptoms, and functional integrity of the immune system. Recommendations for the treatment of children with histoplasmosis are reviewed in Table 250.2. Inasmuch as controlled trials have not been performed in children, most recommendations for treatment are derived from the results of trials conducted in adults and the opinions of experts.[92]

TABLE 250.2

Summary of Treatment Recommendations for Children With Histoplasmosis

Manifestation	Moderately Severe or Severe Illness	Mild to Moderate Illness
Acute pulmonary type	AMB[a] for 1–2 wk, then ITR[b] for 12 wk Corticosteroids appear to be beneficial in patients with high-inoculum disease	Symptoms <4 wk: none Persistent symptoms >4 wk: ITR for 6–12 wk[b]
Disseminated disease (non-HIV)	AMB[a] for 1–2 wk, then ITR for at least 6 mo[c]	ITR for 6–18 mo or the same as for severe illness[b]
Disseminated disease (HIV)	LAB for 1–2 wk, then ITR for life[d]	
CNS histoplasmosis	LAB for 4–6 wk, then ITR for 12 mo[b]	
Granulomatous mediastinitis	AMB[a] for 1–2 wk, then ITR for 6 mo	ITR for 6–12 mo
Fibrosing mediastinitis	ITR for 3 mo[e]	Same as for severe illness
Pericarditis	Pericardial drainage for severe tamponade plus an NSAID for 2–12 wk[f]	NSAID for 2–12 wk
Rheumatologic	NSAID for 2–12 wks	Same as for severe illness
Compression of contiguous structures by granulomatous lymphadenopathy.	Symptoms <4 wk: none Persistent symptoms >4 wk: ITR for 6–12 wk[g]	

[a] Liposomal amphotericin B (LAB) or deoxycholate AMB. Many clinicians prefer the use of LAB because it has a lower frequency of infusion-related adverse reactions and nephrotoxicity.

[b] Itraconazole drug level monitoring is needed. Itraconazole suspension has higher

bioavailability than the capsule form and is the preferred agent for follow-up itraconazole treatment.

[c] Therapy should continue until the *Histoplasma* antigen concentration in serum is undetectable and the *Histoplasma* urine antigen concentration is less than 2 μg/mL and stable. (Low urine concentrations can be present for extended periods after successful therapy.)

[d] See text regarding discontinuation of secondary prophylaxis after combination antiretroviral therapy.[97]

[e] Probably ineffective if fibrotic. When granulomatous mediastinitis could be present, ITR may be considered.

[f] Indomethacin is the preferred NSAID.

[g] Corticosteroids may be beneficial in reducing the effect of compression. If used, ITR also should be used.

AMB, amphotericin B; CNS, central nervous system; FLU, fluconazole; HIV, human immunodeficiency virus; ITR, itraconazole; LAB, liposomal amphotericin B; NSAID, nonsteroidal anti-inflammatory agent.

Healthy children whose chest radiographs show findings compatible with previous histoplasmosis require no therapy. Symptomatic histoplasmosis in immunocompetent children usually is self-limited, and few children benefit from antifungal treatment. Disease manifestations that uniformly require therapy in otherwise immunocompetent children are progressive disseminated infection and serious respiratory infections resulting from high-inoculum exposure. Other infections for which antifungal therapy often is used are pulmonary infection with clinical symptoms that last longer than 4 weeks and granulomatous adenitis that obstructs or occludes blood vessels, bronchi, the esophagus, or other critical structures. The lymphocytolytic effect of corticosteroids can provide prompt relief of obstruction; in these instances, concomitant antifungal treatment is needed to prevent progressive dissemination.[47,53,92] Neither antifungal nor corticosteroid therapy is beneficial if inflammation has progressed to fibrosis.[93] Presumed ocular disease, rheumatologic syndromes, and isolated pericarditis do not require antifungal therapy. Patients with *Histoplasma* pericarditis usually improve, sometimes dramatically, with indomethacin.[43,44]

Immunocompromised people with any manifestation of active histoplasmosis should be treated with an antifungal agent because the risk for progressive dissemination is high. Asymptomatic patients in whom a biopsied pulmonary nodule reveals granulomatous inflammation, sometimes containing typical yeast-like organisms, do not benefit from treatment.[78]

Amphotericin B is the preferred agent for initial treatment of severely ill patients because it induces a faster clinical response than the azole agents.[94] However, the effectiveness, convenience of administration, and lesser toxicity of the azoles have established their important therapeutic roles.[95] Azoles can be used either as consolidation therapy after induction with amphotericin B, or as monotherapy in mildly or moderately ill patients.[92] In patients with progressive, disseminated infection, antigenuria should be monitored at monthly intervals to ensure that the urine antigen level decreases. Low-level antigenuria (<2 ng/mL) can persist in asymptomatic infants for several weeks after adequate treatment for disseminated histoplasmosis.[57] In these instances, antifungal therapy can be stopped safely, provided the infant is clinically well and the recommended duration of treatment has been completed. Such patients should be followed to ensure that antigenuria resolves.

Liposomal amphotericin B has been shown to reduce the duration of fungemia and antigenemia more quickly than itraconazole.[94] A controlled clinical trial in adults with AIDS complicated by disseminated histoplasmosis found that liposomal amphotericin B was associated with improved survival compared with amphotericin B deoxycholate.[96]

Before cART became available, a microbiologic cure could not be achieved reliably in people with HIV infection. Because relapse often occurs after the cessation of antifungal treatment, long-term antifungal suppressive therapy with itraconazole is recommended (see Table 250.2).[92,97] Fluconazole, although not recommended for the treatment of acute infections, can be used for suppression if the patient cannot tolerate itraconazole.[98] Itraconazole results in more rapid sterilization of blood cultures than fluconazole, despite no demonstrable difference in urine antigen clearance. Fluconazole resistance has been reported to develop during therapy.[99] Other azoles (e.g., voriconazole and posaconazole) have been shown to be effective as salvage therapy in a small number of patients. Ketoconazole is not effective.[100–103]

In adult patients who received cART therapy, a controlled trial found that discontinuation of secondary prophylaxis was safe under five conditions: if cART was given for at least 6 months; the CD4$^+$ T-lymphocyte count was higher than 150 cells/mm^3; antifungal therapy had been given for 1 year; fungal blood cultures were negative; and serum and urine *Histoplasma* antigen levels were below 4.1 units.[104] Candidates for long-term antifungal suppression include patients with histoplasmosis who have cellular immune disorders not induced by HIV and in whom antigenuria persists or relapse occurs after adequate therapy.

Echinocandins (e.g., caspofungin and micafungin) lack adequate activity against *H. capsulatum*.[105,106]

Large necrotic masses that do not diminish with medical treatment should be drained only if they obstruct critical structures.[107] Excision of densely fibrotic lesions involving the lung parenchyma, blood vessels, and/or bronchi is rarely helpful and is associated with a high risk of uncontrolled hemorrhage.[108]

Special Considerations

Adrenal insufficiency, nephrocalcinosis, and hypercalcemia (perhaps caused by hypersensitivity to vitamin D) have been associated with disseminated infections. Gastrointestinal tract ulcerations can cause bleeding, mimic neoplastic disorders, or obstruct the gastrointestinal or biliary tracts. Transplacental infection was reported in an infant born to a mother infected with HIV who had disseminated histoplasmosis during pregnancy.[109] Presumed ocular histoplasmosis is a destructive retinal lesion; evidence that this disorder is caused by histoplasmosis is weak.[110,111] Presumed ocular histoplasmosis, mediastinal fibrosis,[112] chronic histoplasmosis, osteomyelitis,[54] central nervous system infection,[55,56,113–115] and endocarditis[116] are manifestations that occur almost exclusively in adults. Cavitary pulmonary lesions are observed in adults with preexisting lung disease (e.g., emphysema) but are seen rarely in immunocompetent, previously healthy children. A superior vena cava syndrome that occurred secondary to mediastinal fibrosis and required placement of an intravascular stent was described in a young child with T-lymphocyte deficiency.[117]

Prevention

In endemic regions, patients with cellular immunodeficiencies or HIV infection and people who receive immunosuppressive drugs should be counseled about high-risk activities (see Box 250.1).[97] If such activities are unavoidable, the person should wear a protective mask. Advances in vaccine development have been reviewed in other sources.[118,119]

Key Points

Microbiology, Epidemiology, and Clinical Aspects of Histoplasmosis

Microbiology and Acquisition

- The spore-bearing, mycelial form of *Histoplasma capsulatum* grows in the environment; bird and bat excreta stimulate growth. Inhaled spores convert to the yeast-like (parasitic) form that replicates at 37°C and is recovered from sites of infection.

- Infection results from inhalation of microconidia (spores) produced by the mycelial form of the endemic, dimorphic fungus *H. capsulatum* var. *capsulatum.*

Epidemiology

- Distributed worldwide; highly endemic in the Ohio and Mississippi River valleys of the U.S.

- Infections occur both sporadically and when contaminated sites are disturbed.

Clinical Features

- Severity is proportionate to inoculum size and the degree of functional impairment of cellular immune function; 90% of infections in healthy hosts are subclinical.

- High-inoculum infection may lead to severe pulmonary disease and respiratory failure.

- Common symptoms include low-grade fever, chest pain, weight loss, headache, myalgias, and erythema nodosum (in adolescents).

- Life-threatening, progressive disseminated infection can occur during infancy or in children with acquired or congenital cellular immune dysfunction.

Diagnosis

- In patients who live in or have visited endemic regions, focal pulmonary infiltrates with middle mediastinal lymphadenopathy with or without calcifications is highly suggestive of histoplasmosis.

- Strongly compatible laboratory findings:

▪ Complement fixation antibody titer ≥1 : 32 to yeast or mycelial phase for individuals who reside in an endemic area

▪ Detection of antigen in urine and/or serum

▪ Histopathologic demonstration of granulomatous inflammation associated with yeast-like forms characteristic of *H. capsulatum*

Treatment

- Most mild infections in healthy children resolve without antifungal treatment.

- Nondisseminated infections associated with persistent symptoms can be treated with itraconazole.

- Seriously ill patients, including those with signs of progressive dissemination, require induction therapy with amphotericin B followed by itraconazole.

Pneumocystis jirovecii

Francis Gigliotti, Terry W. Wright

Description of Pathogen

Pneumocystis jirovecii (formerly called *P. carinii*) is an opportunistic parasite that has some of the common features of protozoa, but in which molecular studies have shown greater genetic homology to fungi.[1] *Pneumocystis* organisms have a high degree of host-species specificity; the organisms that infect humans is designated *P. jirovecii*.[2] Alternative acceptable nomenclature retains the use of *P. carinii* but uses the annotation *forma specialis* or *f. sp.* to identify the host of origin; therefore, *P. carinii* that infects humans, rats, or mice would carry the *f. sp.* designation *hominis, ratti,* or *muris*, respectively. Clinicians should be aware that any of these variations may appear in the medical literature.

To date, reliable axenic culture of *Pneumocystis* from any mammalian host has not been achieved. However, specific developmental life forms of *Pneumocystis* have been identified in infected tissue. The 5- to 7-µm cyst contains up to 8 pleomorphic intracystic bodies (sporozoites). Once excysted, sporozoites are believed to become trophic forms (trophozoites). All these forms reside in the alveoli of the lung. Most immunocompetent children have acquired the infection asymptomatically by the age of 4 years. *Pneumocystis* pneumonia (PCP) occurs almost exclusively in severely compromised people, and with rare exceptions the infection remains localized to the lungs. Although pneumonia in immunocompromised patients was presumed to represent reactivation of a latent infection, animal studies have called into question the capacity of *Pneumocystis* to persist as a latent infection.[3]

Epidemiology

Animal-to-animal transmission of *Pneumocystis* by the airborne route has been demonstrated, and DNA sequences identical to those of *Pneumocystis* have been detected in samples of ambient air. Human-to-human transmission has not been proved, but clusters of cases of pneumonia have been reported in immunocompromised patients. Animal-to-human transmission is unlikely because of the well-established genetic and antigenic diversity of the organism related to the host of origin. A natural habitat has not been found, but the infection has a worldwide distribution. Serologic studies have demonstrated that a high proportion of the population has evidence of infection and that seroconversion occurred during childhood. A prospective longitudinal study demonstrated that seroconversion began in the first few months of life and by 20 months of age, 85% of the infants had seroconverted.[4] Animal studies have demonstrated that *Pneumocystis* can be transmitted from healthy host to healthy host, producing very mild disease in the process.[5] This finding, along with the observation of early seroconversion in children, provides a potential explanation of how *Pneumocystis* is maintained in the human population.

Overt disease in the form of pneumonia develops only in immunocompromised people. The occurrence of PCP is related to the extent of immunosuppression, especially impairment of cell-mediated immunity.[6] For example, PCP occurs in about 40% to 50% of infants and children with acquired immunodeficiency syndrome (AIDS) or severe combined immunodeficiency syndrome (SCIDS), in 12% of children with acute lymphocytic leukemia, and in 6% of organ transplant recipients if no prophylaxis is given.

Clinical Manifestations

The signs and symptoms of PCP are directly related to the organisms and to the inflammatory response in the alveolar lumen, septum, or both. Two somewhat different clinical patterns have been observed, which differ only in the intensity of expression.

The endemic infantile form of PCP, originally described in outbreaks in European nursing homes for infants, is an interstitial plasma cell pneumonitis.[7] Its onset is subtle, and it is seen largely in debilitated infants at 4 to 6 months of age. A bronchiolitis-like illness can occur, with prominent tachypnea and dyspnea in the absence of fever. Intercostal retractions are marked, and as the course progresses, flaring of the nasal alae and cyanosis can be observed and crackles are heard bilaterally. In untreated cases the course of the illness is prolonged over many days to a few weeks, and at least half of these patients die.

In older children and adults with an underlying immunodeficiency disorder that is not related to AIDS (e.g., cancer or organ transplantation), PCP begins abruptly with fever, tachypnea, and cough. Intercostal retractions and flaring of the nasal alae can occur, but breath sounds are normal and rales are not heard. The untreated course is progressive, and these patients all die within a month.

The spectrum of clinical manifestations in patients with AIDS can vary from the subtle variety seen in the infantile type to the acute fulminating type. Without treatment the course ends in fatality in almost all patients.

Clinical observations in humans suggest that a poor prognosis in PCP correlates with evidence of inflammation. For example, an elevated level of neutrophils or interleukin-8 in bronchoalveolar lavage fluid correlates with poorer oxygenation and a lower survival rate. Some insight into these observations comes from animal models. Physiologic studies of mice with SCIDS demonstrate that lung injury (decreased compliance, hypoxia, and surfactant dysfunction) is directly related to the *Pneumocystis*-specific inflammatory response rather than to the organism burden per se.[8] In addition, $CD8^+$ T lymphocytes appear to be critical to causing injury in the absence of effective $CD4^+$ T-lymphocyte–mediated immunity. Therefore, developing better means of controlling the inflammatory response could result in an improved outcome for patients with PCP.

Laboratory Findings and Diagnosis

In all clinical types of PCP the arterial oxygen tension (PaO_2) is decreased and reflects the severity of the disease. In moderately severe cases the PaO_2 is below 70 mm Hg and the alveolar-arterial oxygen gradient is above 35 mm Hg. The white blood cell count is unaffected by the infection. In patients with AIDS-related PCP, the $CD4^+$ T-lymphocyte count is usually below the normal range and often is below 200 cells/mm^3 in patients older than 6 years of age. In patients taking immunosuppressive medicines, determining the risk of PCP based on $CD4^+$ T-lymphocyte counts is complicated by the fact that the $CD4^+$ cells present may not be fully functional.

The role of antibody in the control of *Pneumocystis* has been underappreciated. Early descriptions of patients with PCP included patients with primary antibody deficiencies.[9] Patients with hyper-IgM syndrome now are known to be at high risk for PCP.[10,11] These patients lack the CD40 ligand on their T lymphocytes; consequently, these cells are unable to interact properly with B lymphocytes for the production of specific IgG. Mouse models have confirmed the importance of antibody. For example, blocking the CD40 ligand in mice prevents resolution of PCP, a finding consistent with observations in patients with hyper-IgM syndrome.[12] B-lymphocyte–deficient mice (MuMT), which are incapable of normal antibody production but largely have preserved T-lymphocyte function, are naturally susceptible to *Pneumocystis*.[13] Passive administration of *Pneumocystis*-specific antibody to immunosuppressed mice limits the extent of infection.[14]

The chest radiograph typically shows bilateral alveolar disease, which first appears in the perihilar area and then progresses peripherally, often sparing the apical areas (Fig. 251.1). In some cases no radiographic abnormality is detectable at the onset of symptoms. Definitive diagnosis requires demonstration of *Pneumocystis* in the pulmonary parenchyma or in fluid from the lower respiratory tract.[15] The least invasive method for obtaining diagnostic specimens is to induce sputum. This procedure requires the cooperation of the patient and usually is limited to children 5 years of age or older. Typically, 20 to 30 minutes of inhaling a nebulized mist of 3% saline from an ultrasonic nebulizer is required to stimulate adequate expectoration. The sputum specimen is diluted 1 : 1 in sterile saline, treated with dithiothreitol, and processed for cytologic examination and culture. About 20% to 40% of specimens reveal organisms in patients with PCP (Table 251.1). The organism is more likely to be found in the sputum of PCP patients who have AIDS than in those who do not have AIDS because of the greater infectious burden in the former condition.

fever and congestion. The physical examination revealed tachypnea, retractions, flaring, and hypoxia but no rales. A plain radiograph shows bilateral diffuse air-space lung disease (A), which progressed peripherally over 2 days (B). Note apical sparing. (Courtesy E.N. Faerber, J. Chen, and J. Specimens Tested to Aid Identification of *Pneumocystis* Infection

Method	Sensitivity (%)[a]	Comments
Induced sputum	20–40	≥5 yr
Tracheal aspirate	50–60	First step in intubated patients
Fiberoptic bronchoscopy bronchoalveolar lavage	75–95	Procedure of choice in most patients; both bronchoalveolar lavage and biopsy procedures are preferred
Transbronchial biopsy	75–95	
Open-lung biopsy	90–100	Most sensitive and informative specimen

[a] Estimates of the percentage of specimens expected to be positive in cases of *Pneumocystis* pneumonia.

Bronchoalveolar lavage (BAL) is the method of choice for most patients because it can be performed through a flexible fiberoptic bronchoscope using topical 1% lidocaine anesthesia. A transbronchial lung biopsy also can be performed at the time of bronchoscopy. A successful biopsy should provide at least 20 alveoli for study. With the use of these two procedures, PCP can be identified in nearly 100% of cases.

Open-lung biopsy provides a larger specimen for evaluation of the histopathology of the disease process and for identification of viruses, bacteria, and fungi. However, open biopsy has the disadvantage of requiring general anesthesia and can be complicated by pneumothorax and bleeding.

Specimens should be stained with Giemsa, Grocott-Gomori, or fluorescein-labeled antibody stains (Fig. 251.2). Other useful stains include toluidine blue O and Gram-Weigert stains. Specimens also should be inoculated onto culture media for bacteria and fungi and onto shell viral culture for viruses (especially cytomegalovirus). Many research laboratories are performing polymerase chain reaction testing to identify *Pneumocystis* in a sputum or BAL sample. These investigations may lead to diagnostic assays that can be adapted to clinical laboratories.

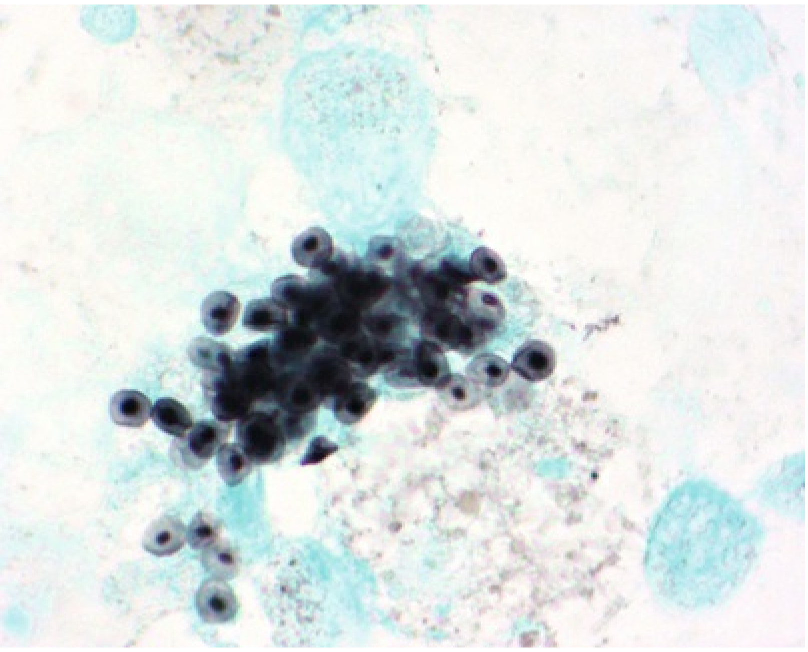

FIGURE 251.2 A bronchoalveolar lavage specimen, stained using the Grocott-Gomori method, shows the dark staining (brown to black) of *Pneumocystis* cysts. These cysts measure 5 to 6 μm in diameter. This method stains background tissue light green.

Special Considerations

Under certain circumstances, forgoing an invasive diagnostic procedure and treating the patient on the basis of a presumptive diagnosis of PCP may be prudent, such as in children with terminal stages of untreatable cancer and patients with uncontrollable bleeding disorders. When an invasive diagnostic procedure is planned, knowing that *Pneumocystis* persists in the lungs for many days after the onset of specific therapy is useful; therapy can be initiated immediately and the procedure performed hours later under optimal circumstances.

Treatment

Table 251.2 presents the drugs and dosage schedules used in the treatment of PCP. Trimethoprim-sulfamethoxazole (TMP-SMX), the drug of choice, is available both for oral and for intravenous therapy. The oral route of administration can be used in mild cases if the patient can take and retain oral medication dependably. However, most patients require at least initial treatment by the intravenous route. The course of treatment is 2 to 3 weeks for most children. Because all immunocompromised patients require posttreatment prophylaxis, the dose of TMP-SMX is reduced to the prophylaxis dose after recovery and continued indefinitely or until the immunodeficiency has resolved.

[a] General duration of therapy is 3 weeks in patients with AIDS and 2 weeks in other immunosuppressed patients. Prednisone is recommended as adjunctive therapy to any antimicrobial therapy for moderate or severe *Pneumocystis* pneumonia (room air arterial oxygen tension ≤70 mmHg or an alveolar-arterial gradient ≤35 mmHg).

IV, intravenous; PO, orally; TMP-SMX, trimethoprim-sulfamethoxazole.

Adverse reactions to TMP-SMX are uncommon in patients without AIDS (~5%) but occur frequently in children with AIDS (~40%). An erythematous, maculopapular rash is the most common adverse effect. The rash often is transient and may clear without withdrawal of the drug; however, progressive intensive rashes, especially urticaria, require discontinuation of the drug. In rare cases, Stevens-Johnson syndrome can occur secondary to the sulfonamide and can have serious consequences. Other adverse effects include neutropenia, megaloblastic or aplastic anemia, renal dysfunction, nausea, vomiting, and diarrhea.

Patients who cannot tolerate or who fail to respond to TMP-SMX should be treated with intravenous pentamidine isethionate. If intravenous access is not available, the drug can be given by deep intramuscular injection, but serious reactions at the injection site are common (e.g., soft tissue necrosis and abscess). Other adverse reactions, which occur in up to 70% of cases, include renal and hepatic dysfunction, thrombocytopenia, anemia, hypotension, abnormally high or low blood glucose concentrations, and rash.

Several other drugs have been shown to have activity against *Pneumocystis* but have not been studied extensively in children. They include atovaquone, an oral hydroxynaphthoquinone; trimetrexate, a drug for intravenous use that must be given concomitantly with leucovorin; TMP-dapsone, given orally; pyrimethamine-sulfadoxine (Fansidar), given orally; clindamycin plus primaquine, given orally; and aerosolized pentamidine.

Supportive measures are important in the management of PCP. The PaO_2 should be maintained above 70 mm Hg; in addition, if possible, the inspired oxygen fraction (FiO_2) should be kept below

50 vol%. If the PaO_2 cannot be maintained at 60 mm Hg or higher, assisted ventilation usually is indicated. Anemia should be corrected with a packed red blood cell transfusion.

Several studies in adults suggest that administration of a corticosteroid in severe and moderately severe cases of PCP improves survival. Limited data in children indicate similar effects.[16] It is reasonable to consider corticosteroid administration at the onset of treatment in patients with a PaO_2 below 70 mm Hg or an alveolar-arterial gradient of 35 mm Hg or greater. Methylprednisolone (2 mg/kg/day) has been used in children. The dose should be tapered and the corticosteroid discontinued in the recovery stage of the pneumonia. The corticosteroid's effect in this setting probably is modulation of the inflammatory response.

The animal data[8] linking pulmonary morbidity with the *Pneumocystis*-induced inflammatory response suggest that better means of controlling this inflammatory response could result in improved outcomes in patients with PCP.

Prevention

Four drugs are available for the prevention of PCP (Table 251.3). TMP-SMX or aerosolized pentamidine is used most frequently, but only TMP-SMX has been studied in children. Comparative studies in adults show that TMP-SMX is superior to aerosolized pentamidine for preventing PCP in patients with AIDS, although the frequency of adverse reactions is greater with TMP-SMX. The prophylactic dose is 5 mg TMP and 25 mg SMX/kg/day in 2 divided doses. The drug can be given daily or only 3 days per week. The 3-day schedule should be on consecutive days, such as Monday, Tuesday, and Wednesday.[17] Some evidence suggests that TMP-SMX may prevent certain bacterial infections in addition to *Pneumocystis*. If this effect is sought, the daily dosage schedule should be used.

TABLE 251.3

Recommended Prophylaxis for Recurrence of *Pneumocystis* Pneumonia After Treatment in HIV-Infected Infants, Children, and Adolescents

Age Category	First Choice	Alternatives

Infants and children	TMP-SMX orally	Dapsone orally *or* Aerosolized pentamidine *or* Pentamidine intravenously
Adolescents	TMP-SMX orally	Dapsone orally *or* Dapsone + pyrimethamine + folinic acid orally *or* Aerosolized pentamidine *or* Atovaquone orally

TMP-SMX, Trimethoprim-sulfamethoxazole.

For patients who cannot tolerate TMP-SMX, aerosolized pentamidine can be tried in children who are old enough and able to cooperate with administration.[18] Most children age 5 years or older can tolerate treatment with aerosolized pentamidine. A dosage has not been established, but 300 mg delivered in a Respirgard II nebulizer once monthly is reasonable and well tolerated. The main adverse effects are cough and bronchospasm. For patients ≤5 years of age and those who cannot tolerate aerosolized pentamidine or TMP-SMX, dapsone given orally at a dosage of 2 mg/kg/day or 4 mg/kg once weekly can be used. Dapsone is effective in preventing PCP, but adverse reactions similar to those caused by sulfonamides can occur. The total dosage should not exceed 100 mg per day, or 200 mg weekly. Atovaquone at a dose of 1500 mg given orally once daily appears to be equal to pentamidine and dapsone for preventing PCP in adults. Atovaquone has not been well studied in children; however, a dosage of 30 mg/kg once daily is suggested for children 1 to 3 months of age, and for those older than 24 months of age; a dosage of 45 mg/kg once daily is suggested for children 4 to 24 months of age.[19]

Several risk factors for PCP have been recognized, and these guide the selection of candidates for prophylaxis. Prophylaxis is important for immunosuppressed patients who have had one episode of PCP; children with severe cell-mediated immunodeficiency, such as occurs with SCIDS, organ transplantation, and AIDS; and children with lymphoproliferative malignancies and other types of malignancy that require intensive chemotherapy.

In infants and children with AIDS, the CD4$^+$ T-lymphocyte count or percentage can be used as the criterion for primary prophylaxis.[19] However, approximately one half of the cases of PCP in infants with AIDS occur as the initial manifestation of AIDS, with a high mortality. All infants exposed to or infected with HIV should receive PCP prophylaxis between 1 month and 1 year of age, or until HIV infection has been ruled out, because of the high risk of pneumonia in this age group. After 1 year of age the CD4$^+$ lymphocyte count and percentage serve as the guide (Table 251.4).

TABLE 251.4

Recommended Primary Prophylaxis for *Pneumocystis* Pneumonia in HIV-Infected Infants and Children by Age and CD4$^+$ Count or CD4$^+$ Percentage

Age	CD4$^+$ Count	CD4$^+$ %
1–12 mo	All infants	All infants
12–23 mo	<750/mm^3	<15
24 mo–5 yr	<500/mm^3	<15
≥6 yr	<200/mm^3	<15

Chemoprophylaxis does not ensure complete protection from PCP. Breakthrough infections occur in at least 6% of those treated with TMP-SMX and in about 12% of those receiving aerosolized pentamidine or oral dapsone. For children who have adverse reactions to TMP-SMX, desensitization can be attempted by escalating from extremely small doses to full doses.[20] This approach has been applied successfully in patients with AIDS. Prophylaxis is effective only during the intervals when the patient is taking the drug; therefore, an effort must be made to ensure adherence in high-risk patients and to continue prophylaxis when patients are hospitalized.

In adults with HIV infection who are receiving combination antiretroviral therapy, primary and secondary prophylaxis against PCP can be discontinued safely after the CD4$^+$ lymphocyte count has been 200/mm^3 or higher for longer than 3 months.[21] A similar approach is recommended for children who have received at least 6 months of combination antiretroviral therapy and whose CD4$^+$ lymphocyte counts have returned to normal levels for age.[19]

Key Points

Diagnosis and Management of *Pneumocystis* Pneumonia

Microbiology

- Fungal organism that cannot be grown in culture
- Displays tight host-species specificity

Epidemiology

- Acquired by inhalation
- Key risk factor is decreased lymphocyte number or function or both.

Diagnosis

- Hypoxia is the pathognomonic feature.
- Based on demonstration of *Pneumocystis* organisms in a pulmonary specimen

Treatment

- Trimethoprim-sulfamethoxazole is the drug of choice.
- Response to treatment is slow, typically 4–5 days.

Duration of Therapy

- Three weeks for patients who have AIDS or other forms of severe immunosuppression
- Two weeks for other patients

Blastomyces dermatitidis (Blastomycosis)

Gregory M. Gauthier, Bruce S. Klein

Blastomyces dermatitidis, the etiologic agent of blastomycosis, can infect both people with healthy immune systems and those with impaired immune defenses. Most infections are sporadic; however, 16 outbreaks have been reported, of which 13 involved pediatric patients.[1–16] An estimated 2% to 13% cases of blastomycosis occur in patients 18 years old or younger.[17–23] Clinical manifestations of blastomycosis range from asymptomatic infection to acute pneumonia, chronic pulmonary infection, disseminated disease, and acute respiratory distress syndrome[1,24,25]

Microbiology

B. dermatitidis belongs to a group of human pathogenic fungi that undergo a temperature-dependent conversion between two distinct morphologic forms, mycelia and yeast.[26] In the soil (22°C to 25°C), *B. dermatitidis* grows as septated mycelia (1 to 2 μm in diameter) that produce infectious spores (4 to 5 μm in diameter).[27,28] Soil disruption by human activities (e.g., construction) aerosolizes mycelial fragments and spores, which convert to yeast when inhaled into the lungs of a human host (37°C).[26] *B. dermatitidis* yeast, which are 8 to 15 μm in size, have a distinct morphologic appearance characterized by a broad-based bud and a refractile (i.e., double-contoured) cell wall (Fig. 252.1).[27,28]

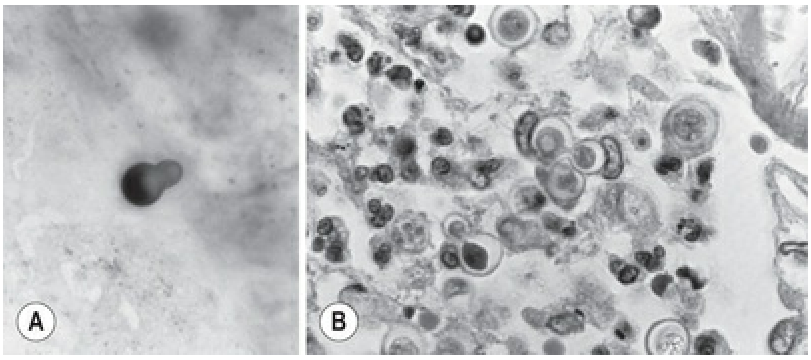

FIGURE 252.1 (A) Cutaneous blastomycosis. Touch preparation of a skin biopsy showing a single *Blastomyces dermatitidis* yeast-like cell with a broad-based bud. Gomori methenamine silver nitrate stain, ×1000. (B) Acute pulmonary blastomycosis. Single yeast-like cells with doubly contoured walls and two prominent, budding yeast-like cells of *B. dermatitidis* seen in a suppurative exudate. In histopathologic sections of involved tissues, finding yeasts 8 to 15 μm in diameter with single, broad-based buds is considered diagnostic. The inflammatory reaction can be acute, suppurative, or granulomatous. Hematoxylin and eosin, ×1000.

In addition to growing as mycelia or yeast, *Blastomyces* organisms exist in an asexual (imperfect, anamorphic) state or a sexual (perfect, teleomorphic) state. *B. dermatitidis* is the name for the asexual state, and *Ajellomyces dermatitidis* is the name for the teleomorphic state.[29] Sexual reproduction in *B. dermatitidis* occurs in the mycelial phase when hyphae with different mating-type loci (e.g., MAT1-1 and MAT1-2) fuse and form specialized reproduction structures.[29] Although mating contributes to genetic diversity, its impact on virulence is unknown.[29,30] Recent molecular analysis of clinical and environmental isolates suggests that *Blastomyces* can be divided into two phylogenetic species, *B. dermatitidis* and *B. gilchristii* sp. nov.[31]

Pathogenesis and Immunity

The reversible switch between mycelial and yeast morphologies is critical to the biology and life cycle of *B. dermatitidis* and those of other thermally dimorphic fungi.[30] Growth as mycelia (22°C to 25°C) promotes environmental survival and transmission to new hosts by infectious spores, in addition to genetic diversity through sexual reproduction.[30] Growth in the yeast phase (37°C) facilitates evasion of hosts' immune defenses.[30] Inhaled spores are phagocytosed by pulmonary macrophages and converted to yeast organisms, which survive and replicate within macrophages during the early stages of *Blastomyces* infection.[32] Extrapulmonary dissemination occurs by lymphohematogenous spread, and in children this most commonly affects the skin and bones.[33]

Genetic regulation of the morphologic switch between mycelial and yeast forms has been the focus of intense research, given the importance of this event on pathogenesis. The discovery of dimorphism-regulating kinase-1 (*DRK1),* which encodes a histidine kinase, provided the first genetic proof (by deletion experiments in the mouse model) that the conversion from mycelia (or spores) to yeast was essential for virulence.[34] The function of *DRK1* also is conserved in other dimorphic fungi, such as *Histoplasma capsulatum* and *Talaromyces marneffei* (formerly *Penicillium marneffei*).[34,35] The reverse morphologic switch, from yeast to mycelia, is regulated by a transcription factor encoded by *SREB* (siderophore biosynthesis repressor in *Blastomyces*) and is influenced by N-acetylglucosamine transporters *NGT1* and *NGT2*.[36,37]

In the yeast phase an immunogenic protein encoded by *Blastomyces* adhesin-1 (*BAD1,* formerly *WI-1*) is upregulated and is essential for virulence in the mouse model; also, its structure has been defined.[38–41] BAD1 functions as an adhesin that binds yeast cells to host tissue and acts as an immune evasin to downregulate host immune defenses.[40] The core tandem repeats bind heparin sulfate in host tissues to promote adherence of yeast.[40] Soluble and cell wall–bound BAD1 bind CR3 and CD14 receptors, impairing production of tumor necrosis factor-α (TNF-α) by macrophages and neutrophils.[42–44] BAD1 also inhibits activation of CD4$^+$ T lymphocytes, reducing production of interferon γ (INFγ) and interleukin-17 (IL-17).[40] The ability of BAD1 to induce a humoral immune response has been used to develop a new sensitive and specific serologic test for diagnosis of blastomycosis.[45]

The cells of the innate and adaptive immune system are critical for host defense against *B. dermatitidis* infection, whereas humoral immunity is dispensible.[46] Alveolar macrophages and neutrophils are capable of killing some, but not all, spores inhaled into the lungs. Spores that survive the initial host response germinate as yeast organisms, which are relatively resistant to reactive oxygen species, suppress nitric oxide production, inhibit cytokine production, and impede CD4$^+$ T-lymphocyte activation.[40,43,44,47–49] Despite the ability of *B. dermatitidis* to modulate host immune responses, Th1 and Th17 T lymphocytes can activate macrophage fungicidal activity to successfully combat infection in some patients.[50,51] Approximately 50% of those infected with *B. dermatitidis* develop asymptomatic or subclinical infections.[1] After recovery from blastomycosis, children and adults develop T-lymphocyte–mediated immunity against *B. dermatitidis* that can last for at least 2 years.[52]

Epidemiology

The lack of reliable skin and serologic tests, difficulty in isolating the fungus from the environment, and reliance on passive surveillance and retrospective studies have hampered the development of in-depth epidemiologic knowledge about *B. dermatitidis*.[53] Currently blastomycosis is reportable in only 6 of the United States and in 2 Canadian provinces. Although underestimated, the incidence of blastomycosis ranges from 0.2 to 1.94 cases per 100,000 population annually.[18,20,54–59] The geographic range of *B. dermatitidis* in North America includes the Mississippi River and Ohio River basins, areas along the St. Lawrence River in New York, the southeastern U.S., and 4 Canadian provinces (Fig. 252.2). In the endemic region *B. dermatitidis* grows in an ecologic niche near freshwater sources (rivers, streams, lakes) that have sandy soils with an acidic pH and decaying vegetation or rotting wood.[1,12,60–63] Although rare, autochthonous cases of human blastomycosis have been reported from Africa (approximately 100 cases) and India (fewer than 10 cases).[64–69]

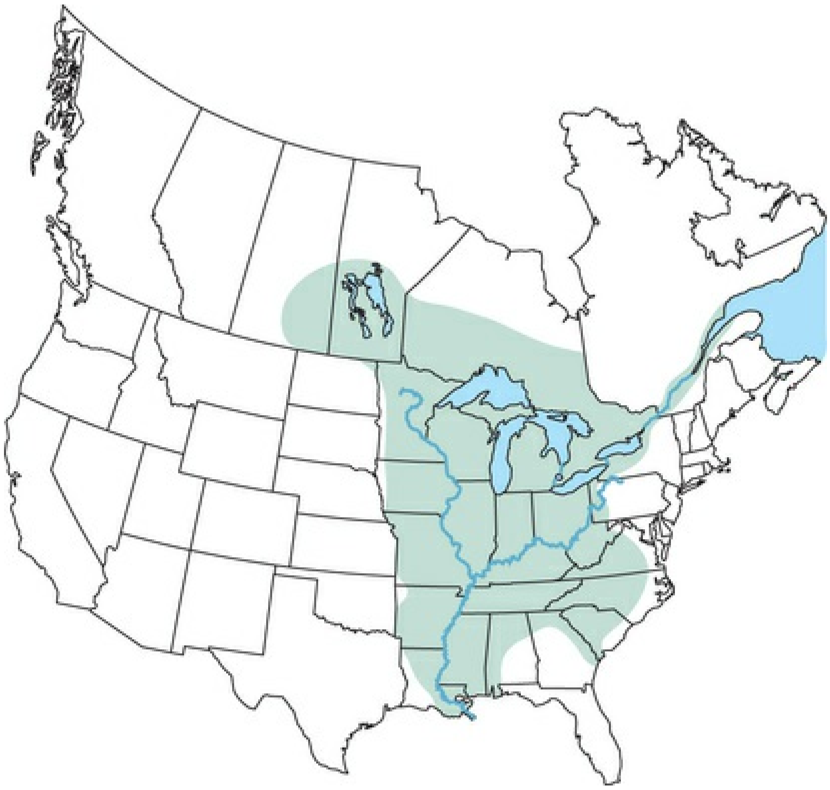

FIGURE 252.2 Map of North America showing the endemic region for infection. Shaded area on the map represents the endemic region. (From Gauthier GM. *Blastomyces dermatitidis* and blastomycosis. In: Sullivan DJ, Moran GP [eds]. Human Pathogenic Fungi. Caister Academic Press, Norfolk, U.K., 2014.)

The vast majority of patients with blastomycosis acquire the infection by inhaling spores and mycelial fragments after disruption of the soil. Activities associated with acquisition in sporadic or outbreak settings include home remodeling, road construction, hunting, clearing brush and cutting trees, using a community compost pile, exploration of underground forts and beaver dams, and canoeing or fishing in endemic regions.[1–16,55] In rare cases, *B. dermatitidis* infection can result from cutaneous trauma (e.g., laboratory accident, bite of an infected dog) or perinatal exposure.[62] Although most cases of blastomycosis are sporadic, 16 well-described outbreaks have been reported.[1–16]

Clinical Manifestations

The incubation period for blastomycosis ranges from 3 weeks to 3.5 months.[1,17,70] The average age of pediatric patients with blastomycosis is 9 to 12 years (range, 18 days to 18 years).[24,33,71–74]

Blastomycosis is rare in neonates and infants.[75] In most studies the gender distribution is skewed toward males.[24,33,71,72,74]

Clinical manifestations of pulmonary infection are variable and include nonspecific symptoms, such as headache, cough, chest pain, weight loss, fever, abdominal pain, and night sweats (Table 252.1)[17,24,71] In two recent case series, 38% to 53% of patients with sporadic blastomycosis had disseminated disease.[24,71] The skin, bone, and central nervous system (CNS) were the most common sites of extrapulmonary infection (Table 252.1). In contrast, disseminated disease in children infected in an outbreak setting is rare (Table 252.1).[1,17] Pulmonary blastomycosis can be complicated by respiratory failure, acute respiratory distress syndrome, and death. The full clinical spectrum of blastomycosis is summarized in Fig. 252.3.[76]

Acute and Chronic Pulmonary Infection.

Acute pulmonary infection is the most common manifestation of blastomycosis in children.[24,33,71–74,77] The spectrum of severity ranges from mild or no illness (Fig. 252.4) to respiratory failure, including acute respiratory distress syndrome.[25,75,77] Symptoms often mimic community-acquired pneumonia and include fever, chills, a productive cough with or without hemoptysis, shortness of breath, chest pain, and malaise.[17,24,71,73,78] Cutaneous findings (e.g., plaques, nodules, or ulcers) in a patient with pneumonia are highly suggestive of fungal pneumonia, including blastomycosis. Immune-mediated cutaneous findings (e.g., erythema nodosum or erythema multiforme), which can be observed in patients with histoplasmosis or coccidioidomycosis, are rare with blastomycosis.[78,79] Unrecognized or untreated acute pulmonary blastomycosis can lead to chronic pneumonia, characterized by fever, night sweats, weight loss, cough, and chest pain. Chronic pulmonary blastomycosis mimics tuberculosis, other mycoses, and neoplasms.

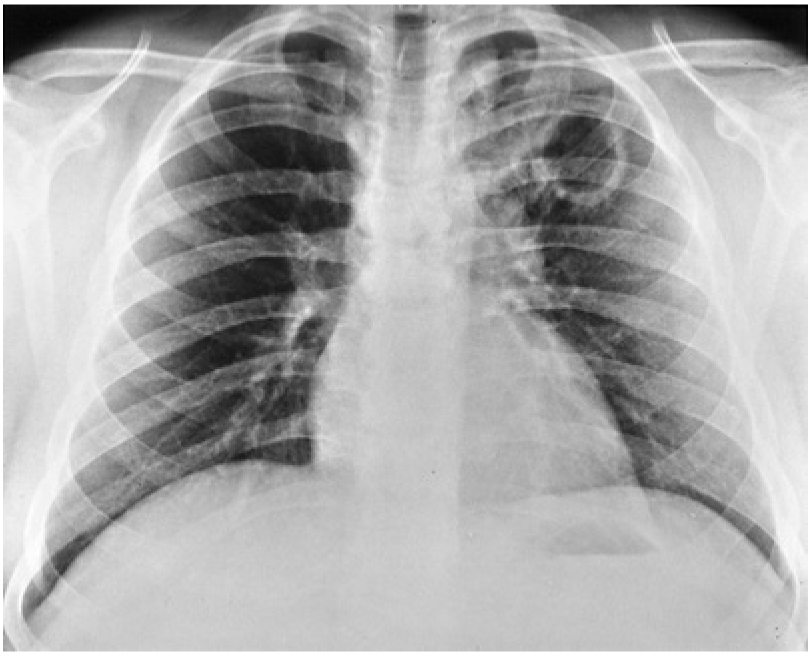

FIGURE 252.4 Chest radiograph of an 18-year-old man with insulin-dependent diabetes mellitus who had hemoptysis of 2 days' duration; he described no fever and no antecedent respiratory symptoms. The radiograph shows a large cavitary lesion in the left upper lobe and enlargement of a left hilar lymph node (hilar lymphadenopathy is uncommon in pulmonary blastomycosis).

Radiographic manifestations are heterogeneous and nonspecific. The most frequent radiographic pattern is consolidation, which is indistinguishable from that seen in community-acquired pneumonia.[71,80,81] Nodular and interstitial infiltrates also are common. Masses and cavities, which mimic malignancy and tuberculosis, are infrequent in children.[71,80,81] Hilar lymphadenopathy and calcification are rare in blastomycosis. Pleural effusion is uncommon. In patients with severe disease, radiographic findings can be slow to resolve; however, most patients recover without long-term pulmonary sequellae.[81,82]

Extrapulmonary Manifestations.

Extrapulmonary blastomycosis occurs in more than one half of pediatric patients and can involve any organ. The duration of infection (i.e., time from symptom onset to diagnosis), rather than age, is thought to influence the rate of dissemination.[17,33,71] Most patients with disseminated disease have concurrent pulmonary symptoms or chest radiographic abnormalities; however, pulmonary disease can resolve before disseminated blastomycosis is diagnosed.[24,75]

Cutaneous Manifestations.

Skin lesions are common in disseminated infections, observed most often in sporadic cases and infrequently in outbreak settings.[1,17,83] Cutaneous disease often begins as minimally tender papules that evolve into verrucous or ulcerative lesions; both types can be present simultaneously. Verrucous lesions have raised irregular borders, crusting, and purulent drainage (Fig. 252.5A). In ulcerative forms, borders are sharp and heaped up and granulation tissue and exudate are seen centrally (Fig. 252.5B). Chronic disseminated cutaneous blastomycosis has been reported rarely.[84] Histopathologic findings characteristic of blastomycosis include pseudoepitheliomatous hyperplasia with neutrophilic and granulomatous inflammation (i.e., pyogranulomatous inflammation).[85]

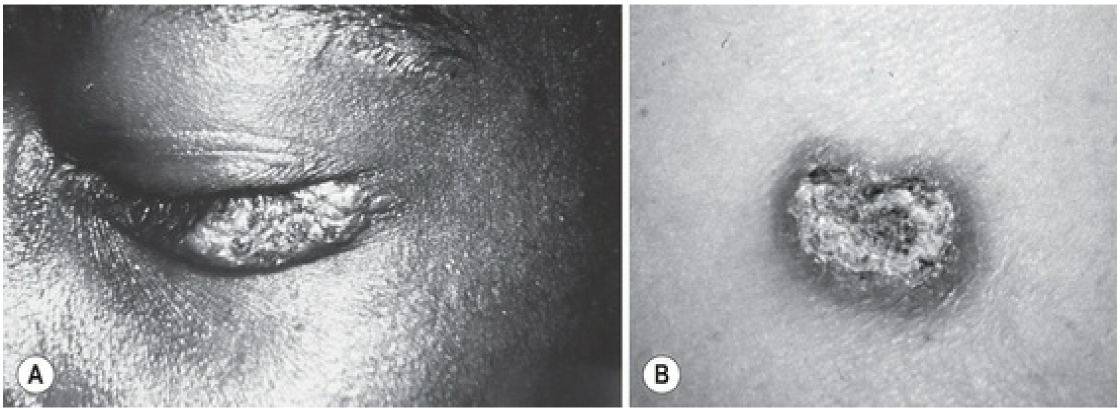

FIGURE 252.5 **Cutaneous lesions of blastomycosis. (A) Verrucous lesion characterized by crusting and induration. (B) Ulcerated lesion.**

Osseous Manifestations.

Acute or subacute suppurative osteomyelitis occurs in 21% to 50% of children with sporadic blastomycosis.[24,33,71] The most commonly affected bones are the long bones (e.g., tibia, femur), vertebral bodies, ribs, and skull (Fig. 252.6).[21,71,74,86–89] Blastomycotic osteomyelitis is characterized by lytic bone destruction with associated bone pain. Complications include pathologic fracture;

vertebral body collapse; soft tissue abscess with or without sinus tract formation; and extension into the joint space, causing septic arthritis.[72,88]

Central Nervous System Manifestations.

Dissemination of blastomycosis into the CNS is uncommon; however, 15% to 18% of patients in two recent case series from the U.S. and Canada had CNS blastomycosis.[24,71] Typically, CNS dissemination occurs in less than 5% to 10% of immunocompetent patients.[21,90] Clinical manifestations include meningitis and abscess, which can be complicated by hydrocephalus, cerebral herniation, mass effect, seizures, and panhypopituitarism.[71,90] Cerebrospinal fluid (CSF) findings include lymphocytic or neutrophilic pleocytosis, an elevated protein level, and a low glucose level.[90] The sensitivity of CSF fungal culture is a suboptimal 45%.[90] In patients with obstructive hydrocephalus, ventricular fluid is more likely to be diagnostic than CSF obtained by lumbar puncture.[91]

Unusual Manifestations.

Rare sites of dissemination include the middle ear, peritoneum, spleen, heart, kidney, larynx, and oral cavity.[72–74,77] Otitis media is frequently due to extension into the middle ear from an extra-auditory site of infection.[92–94] Infections of the prostate gland or epididymis, which occur in adults, have not been reported in prepubescent children.[74]

Laboratory Findings and Diagnosis

The most important "diagnostic test" is to include *B. dermatitidis* as part of the differential diagnosis in patients with pneumonia, cutaneous lesions, or osteomyelitis. Because blastomycosis can mimic infection with neoplasms and either bacteria or mycobacteria, correct diagnosis and initiation of antifungal therapy often are delayed.[21,71,95] Lack of response to therapy for community-acquired pneumonia should raise suspicion. The combination of pneumonia and cutaneous lesions is highly suggestive. Blastomycosis in a family pet provides a diagnostic clue and points to a common-source exposure.[6,96] A detailed history that focuses on determining potential exposures is important; these include residential location, travel, disruption of soil (e.g., home remodeling, road or building construction), outdoor activities (e.g., hunting, fishing, canoeing), logging or tree cutting, and use of community compost.

Mild anemia, leukocytosis (with a mild increase in band forms), and an elevated erythrocyte sedimentation rate are common but nonspecific findings.

Direct Examination and Culture.

A rapid diagnosis can be established through identification of yeast with a broad-based budding pattern in specimens of sputum, bronchial washings, body fluids, or tissue.[53] *B. dermatitidis* is never a commensal. Potassium hydroxide (10% KOH) and calcofluor are used to stain yeast in sputum and body fluids, whereas Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) are used to stain tissue (see Fig. 252.1).[53] *B. dermatitidis* yeast can be difficult to visualize using hematoxylin and eosin staining. Tissue specimens showing neutrophilic infiltration and granulomas should be examined thoroughly for broad-based budding yeast using GMS or PAS stains.

Culture of *B. dermatitidis* from sputum, tissue, or body fluids provides a definitive diagnosis, but growth can take 1 to 4 weeks. In most mycology laboratories, *B. dermatitidis* is incubated at 25°C to 30°C on Sabouraud dextrose agar, brain-heart infusion, or potato dextrose agar.[53] At this temperature, *B. dermatitidis* grows as mycelia and requires confirmatory testing by a chemiluminescent DNA probe assay or exoantigen test, or by conversion to the yeast form at 37°C.[53,97] The latter test is rarely performed because mycelia-to-yeast conversion is slow in vitro. Protocols for reverse transcriptase polymerase chain reaction amplification of BAD1 and *DRK1* have been developed but are not available commercially.[98,99]

Serologic Tests.

Serologic testing by complement fixation or immunodiffusion has poor sensitivity and specificity.[70] In a large outbreak investigation the complement fixation, immunodiffusion, and enzyme immunoassay were positive in 9%, 28%, and 77% of cases, respectively.[1,70] A commercial antibody test based on BAD1 has a sensitivity of 87% and a specificity of 94% to 99%.[45] When this test is used in combination with antigen testing (see next section), the sensitivity increases to 97%.[45]

Antigen Tests.

An antigen assay that detects a galactomannan from the cell wall of *B. dermatitidis* was developed in 2004[100] and has supplanted antibody tests. Appropriate specimens for antigen testing are urine, blood, bronchoalveolar lavage fluid, and cerebrospinal fluid.[100–103] The sensitivity of the antigen test, which is 85% to 93% on urine and 57% to 82% on serum,[101,102] is influenced by the burden of infection. The sensitivity of the urine antigen test is only 50% in localized pulmonary disease.[101] Moreover, cross-reactions are common with *Histoplasma* (96%) and occur rarely with *Aspergillus* and *Cryptococcus*.[100] The BAD1 serologic test has the potential to differentiate blastomycosis from histoplasmosis.[45] Major cross-reactions with *Paracoccidioides* (100%) or *T. marneffei* (70%) are problematic if the patient has traveled or resided in Central or South America, or Southeast Asia, respectively. Although clinical data are limited, antigen levels in the urine or serum can be used to monitor the response to antifungal therapy.[104]

Treatment

Antifungal therapy is recommended for all pediatric patients with blastomycosis. The antifungal selection is based on the severity of the disease, immunocompromise, CNS involvement, and pregnancy.[105] Amphotericin B deoxycholate or lipid products (liposomal amphotericin, ABLC, ABCD) are used in patients with moderate to severe pneumonia, disseminated infection, immunocompromise, or pregnancy.[105] Azole drugs are used as initial therapy for mild disease or as consolidation therapy after 1 to 2 weeks of amphotericin B. Itraconazole is the preferred oral therapy for both children and adults.[105] In a trial of itraconazole 90% of 48 adults with a nonmeningeal, non-life-threatening infection who received doses of 200 to 400 mg/day for 6 months were cured.[106] Voriconazole and posaconazole show good activity in vitro against *B. dermatitidis.*[107] Voriconazole, owing to its excellent penetration into the CNS, has been used successfully in patients with CNS disease who either failed to respond, had a recurrence after treatment, or were intolerant of recommended regimens.[108–111] Posaconazole also has been used successfully to treat blastomycosis.[112] Fluconazole and ketoconazole no longer are recommended for routine therapy because of the high rates of relapse seen with these drugs.[105] Drug interactions, absorption, distribution, and toxicity of the azoles are complex, and knowledge of these issues is essential for successful therapy (see Chapter 293). For example, absorption of itraconazole capsules is optimal if they are taken with food and an acidic beverage, whereas itraconazole solution is administered without food, and is ideal for patients receiving histamine-2 blocking agents or proton pump inhibitors, because gastric acidity is not required for absorption. Itraconazole, voriconazole, and posaconazole require therapeutic drug monitoring and periodic assessment of serum hepatic enzyme levels.[105,113]

Recommendations for treating blastomycosis are derived from clinical trials in adults and the clinical experience of experts. Current clinical practice guidelines for the management of blastomycosis are summarized in Table 252.2 and include recommendations for the treatment of children.[105] In all instances, long-term follow-up is required to identify late dissemination or relapse. The likelihood of adherence to therapy should be assessed before the start of treatment with any oral antifungal agent and should be reassessed if a patient fails to improve.[105]

TABLE 252.2

Summary of Recommendations for Treatment of Blastomycosis

Manifestation/Patient Population	Preferred Treatment	Comments
Moderately severe to severe pulmonary disease	Lipid AMB, 3–5 mg/kg/day, or deoxycholate AMB, 0.7–1 mg/kg/day, for 1–2 wk; then itraconazole,[a] 5–10 mg/kg/day divided twice daily for 6–12 mo	Most clinicians prefer to use azole step-down therapy after clinical improvement; however, the entire course can be given with AMB deoxycholate to a total of 2 g. Lipid AMB formulations have fewer side effects, and duration is not based on total dose received. Perform pregnancy testing for female adolescents before administration of azole. Maximum daily dose of itraconazole is 400 mg.
Mild to moderate pulmonary disease	Itraconazole,[a] 5–10 mg/kg/day divided twice daily for 6–12 mo	Perform pregnancy testing for female adolescents before administration of azole. Maximum daily dose of itraconazole is 400 mg.
Moderately severe to severe disseminated disease	Lipid AMB, 3–5 mg/kg/day, or deoxycholate AMB, 0.7–1 mg/kg/day, for 1–2 wk; then itraconazole,[a] 5–10 mg/kg/day divided twice daily for 6–12 mo	Most clinicians prefer to use azole step-down therapy after clinical improvement; however, the entire course can be given with AMB deoxycholate to a total of 2 g. Lipid AMB formulations have fewer side effects, and duration is not based on total dose received. Treat osteoarticular disease for 12 months. Perform pregnancy testing for female adolescents before administration of azole. Maximum daily dose of itraconazole is 400 mg.
Mild to moderate disseminated disease	Itraconazole,[a] 5–10 mg/kg/day divided twice daily for 6–12 mo	Perform pregnancy testing for female adolescents before administration of azole. Treat osteoarticular disease for 12 months.
Central nervous system disease	Lipid AMB, 5 mg/kg/day for 4–6 wk is preferred[b]; then an oral azole for at least 1 yr	Step-down therapy: *Children 2–12 yr:* fluconazole, 12 mg/kg/day; itraconazole,[a] 10 mg/kg/day; or voriconazole,[c] 9 mg/kg IV every 12 hr (maximum dose, 350 mg every 12 hr) *Children ≥12 yr:* 6 mg/kg every 12 hr loading for 1 day, then 4 mg/kg every 12 hr. Longer treatment

		may be required for immunosuppressed patients.
Disease in immunosuppressed patients	Lipid AMB, 3–5 mg/kg/day, or deoxycholate AMB, 0.7–1 mg/kg/day, for 1–2 wk; then itraconazole,[a] 5–10 mg/kg/day divided twice daily for 12 mo	Lifelong suppressive therapy should be determined on a case-by-case basis. Perform pregnancy testing for female adolescents before administration of azole. Maximum daily dose of itraconazole is 400 mg.
Disease in pregnant women	Lipid AMB, 3–5 mg/kg/day	Azoles should not be used during pregnancy

[a] In any regimen for which itraconazole is used, a random serum concentration should be obtained after 2 weeks of treatment and, if needed, the dosage adjusted to ensure adequate drug exposure. Serum itraconazole level = Itraconazole + Hydroxyitraconazole. Limited information is available about its use in newborns. Adults receive a loading dose of 200 mg orally 3 times a day for 3 days; however, this regimen has not been studied in children.

[b] In animal models of fungal meningitis, liposomal AMB achieves higher CNS levels than other lipid formulations. Hence, many infectious diseases experts recommend liposomal AMB as the preferred lipid formulation for the treatment of CNS fungal infections.

[c] Serum voriconazole trough levels should be obtained to guide proper dosage.

AMB, Amphotericin B; IV, intravenous.

Moderately severe to severe pulmonary disease and/or dissemination in children is treated with a full dosage of either amphotericin B deoxycholate or a lipid formulation for 1 to 2 weeks or longer until improvement occurs.[105] Thereafter, itraconazole is used for 12 months. For these manifestations and any manifestation of blastomycosis for which itraconazole is used, the maximum dose is 400 mg/day; serum concentrations should be determined after 2 weeks of treatment and the dosage adjusted to ensure adequate drug exposure. Children with mild to moderate pulmonary infection can be treated with oral itraconazole for 6 to 12 months.[105] When blastomycosis is diagnosed and treated during pregnancy, the newborn should receive therapy if there is evidence of infection.[105] Although data are limited, amphotericin B should be used for treatment in neonates. Consultation with experts may be needed for unusual or severe cases.

Liposomal amphotericin B is preferred for treating CNS infections because studies in animal models have shown that liposomal formulations attain higher CNS concentrations than other amphotericin B formulations. Treatment should be at full dosage for 4 to 6 weeks, followed by treatment with an azole (fluconazole, itraconazole, or voriconazole) for at least 1 year.[105] A multicenter review of 22 adults concluded that initial treatment with a lipid formulation of amphotericin B and then a prolonged course of an azole, including voriconazole, was effective.[90,114] Most experts recommend voriconazole as consolidation therapy for CNS disease because of its excellent penetration into the CSF compared with itraconazole and its lower minimum inhibitory concentration against *B. dermatitidis* compared with fluconazole. For patients with osteomyelitis, a combination of surgical debridement plus 12 months of antifungal therapy is needed. Surgical drainage also is needed for large abscesses and empyemas because antifungal therapy alone may not be curative.

The echinocandins (e.g., caspofungin, micafungin, anidulafungin) have poor activity against *B. dermatitidis* in vitro because there is minimal biosynthesis of β-(1,3)-glucan in the yeast phase.[115,116] Echinocandins should not be used to treat blastomycosis.[105,117]

Special Considerations

Blastomycosis in pregnancy or in the neonate is uncommon, and clinical data are based on a limited number of case reports.[118–121] Blastomycosis is most frequently diagnosed in the second and third trimesters, and disseminated infection occurs in 62% of pregnant patients.[118] Transmission to the neonate during the peripartum period is poorly understood, and potential routes include transplacental dissemination or aspiration of infected vaginal secretions during delivery.[118–121] All female adolescents diagnosed with blastomycosis must undergo assessment for pregnancy because use of azole agents can result in congenital malformations (fluconazole, voriconazole, posaconazole) and spontaneous abortion (itraconazole).[122–124] In pregnant women and neonates, amphotericin B formulations are the drugs of choice.[105]

B. dermatitidis is considered a primary fungal pathogen because it causes disease in patients with normal and impaired immune systems.[125–129] In an immunosuppressed person, blastomycosis can be newly acquired or can be due to reactivation of latent infection. Most clinical data for blastomycosis in immunocompromised patients is based on case reports and case series in adults. Although blastomycosis is uncommon in patients infected with HIV, severe pulmonary disease and a propensity to disseminate to the CNS occur.[125] For patients immunosuppressed as a result of solid-organ transplantation (SOT), blastomycosis typically manifests as pneumonia, which often is complicated by respiratory failure, acute respiratory distress syndrome, and coinfection with other opportunistic pathogens (most commonly cytomegalovirus).[127,128] Respiratory failure and acute respiratory distress syndrome are associated with high mortality rates, ranging from 33% to 67%.[127,128] Disseminated disease in SOT recipients occurs in 33% to 50% but rarely involves the CNS.[127,128] Blastomycosis also can occur in patients receiving tumor necrosis factor-α inhibiting agents and those with malignancy.[126,129] Antifungal therapy for immunosuppressed patients should consist of an amphotericin B lipid formulation or deoxycholate and then consolidation therapy with an azole (itraconazole, voriconazole, posaconazole) for a total of 12 months. Longterm suppressive therapy should be determined on a case-by-case basis.[105] For SOT recipients, relapse after a proper course of antifungal therapy (e.g., 12 months) is uncommon.[127,128]

Prevention

Immunodeficient patients should be advised of the importance of avoiding exposure to environmental habitats associated with blastomycosis outbreaks when they are counseled about reducing their risk of acquiring opportunistic infections.

Progress in vaccine development has included the generation of a live, attenuated recombinant strain of *B. dermatitidis* that is deficient in BAD1.[130] In a murine model the BAD1-null strain, when administered subcutaneously, induced protective immunity against a lethal pulmonary challenge with *B. dermatitidis*.[130] Moreover, the BAD1-null strain has been used to establish T-lymphocyte–dependent mechanisms and to identify the conserved antigen (calnexin) in the vaccine that promotes protective immunity against *B. dermatitidis* and other thermally dimorphic fungi, including *H. capsulatum* and *Coccidioides* species.[130,131] Currently no vaccine is available.

The authors would like to thank Martin B. Kleiman, M.D. for his authorship of this chapter in the previous editions and acknowledge use of select portions of the fourth edition chapter.

Key Points

Blastomyces dermatitidis Infection

Microbiology

- Thermally dimorphic fungus that converts between mycelia and yeast
- Mycelial form, which produces spores, is the infectious form.
- Growth as yeast facilitates evasion of the immune system and infection in human tissues.
- *BAD1*, an essential yeast phase–specific gene, encodes a multifunctional protein that facilitates adhesion to host cells and suppression of the host's immune defenses.

Epidemiology

- Ecologic niche: sandy soils with an acidic pH that are near freshwater and decaying vegetation
- Activities that disrupt soil, aerosolizing spores that can be inhaled and can convert into yeast, causing pneumonia in healthy and immunocompromised patients
- Blastomycosis can be sporadic or associated with outbreaks.

Clinical Features

- Infections can mimic bacterial and mycobacterial infections and also malignancy.
- Pneumonia is the most common clinical manifestation.
- Dissemination is common and frequently involves the skin and

bone.

Diagnosis

- The most important "diagnostic test" is to include blastomycosis in the differential diagnosis:

▪ Pneumonia that fails to respond to antibiotics

▪ Patients with respiratory failure or acute respiratory distress syndrome who live in or visit endemic regions

▪ Pneumonia with skin lesions

▪ Osteomyelitis involving the spine, ribs, or long bones

▪ Verrucous or ulcerative skin lesions

- A positive travel or exposure history or a pet with blastomycosis

- Tests to establish the diagnosis of blastomycosis

▪ Fungal staining and fungal culture of clinical specimens

▪ *Blastomyces* antigen test of urine, serum, bronchoalveolar lavage specimen, or cerebrospinal fluid

Treatment

- Amphotericin B deoxycholate or lipid formulations

- Azole antifungal agents (itraconazole, voriconazole, posaconazole)

- Pregnancy testing should be performed for all adolescent females before azole administration.

Coccidioides immitis and *Coccidioides posadasii* (Coccidioidomycosis)

George R. Thompson III

Coccidioidomycosis is an infection caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii*. These fungi are endemic to the southwestern United States, Mexico, Guatemala, and sporadic regions in Central and South America. Infection is caused by inhalation of highly infectious and environmentally resistant spores after disruption of the soil causes aerosolization of the organisms. Primary infection often is manifested as an acute respiratory illness, although the spectrum of disease ranges from asymptomatic exposure to severe and life-threatening disseminated disease.[1]

The Pathogen

Microbiology

Coccidioides spp. are dimorphic fungi; in soil they exist as spore-forming saprophytic molds, and in vivo they exist in a spherule-endospore (SE) phase (yeast-like phase) (Fig. 253.1). Two species have been identified through phylogenomic characterization. Although these genomic differences clearly delineate two separate species, no phenotypic, antigenic, virulence, or morphologic differences have been described to date. *C. immitis* is found in California and Washington, whereas *C. posadasii* is found in Mexico and areas of Central and South America.[2]

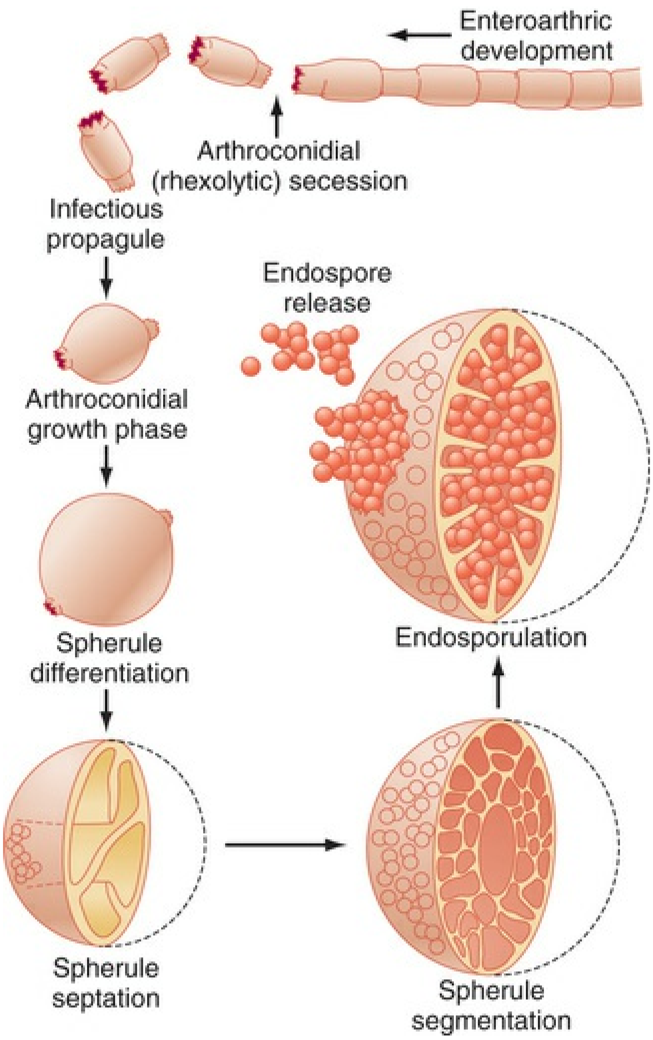

FIGURE 253.1 Life cycle of *Coccidioides immitis.*

(Redrawn from Cole GT, Sun SH. Arthroconidium-spherule-endospore transformation in *Coccidioides immitis.* In: Szaniszlo PJ [ed]. Fungal Dimorphism: with Emphasis on Fungi Pathogenic for Humans. New York, Plenum Press, 1985, p. 281.)

The infectious form of *Coccidioides* consists of desiccated spores (arthroconidia), which are boxcar–shaped structures with thick, hydrophobic walls. Spores are released from the mold when the thin-walled intervening cells disarticulate. After inhalation the spores germinate in the lung and, over 3 to 4 days, become spherules 10 to 80 µm in diameter. Inhalation of only a few spores can cause infection in humans. Spherules undergo internal cleavage and septation and eventually release large numbers of endospores 2 to 5 µm in diameter (Fig. 253.2). The endospores then enlarge, forming spherules, thereby completing the life cycle.[3] Growth of *Coccidioides* is stimulated by progesterone, 17β-estradiol, and testosterone and may significantly affect in vivo growth in the host.[4] The mold form is rarely found in human tissue.

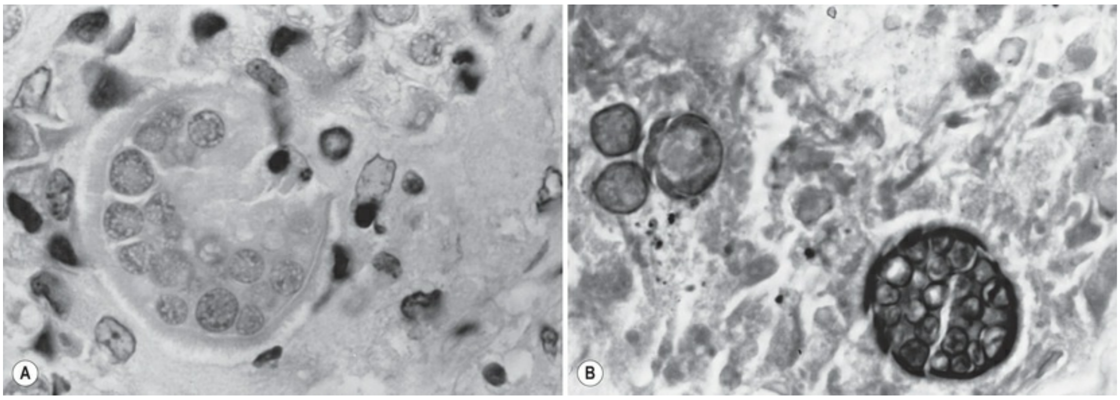

FIGURE 253.2 Specimens from a patient with AIDS who also had pneumonia caused by *Coccidioides immitis.* (A) Ruptured endosporulating spherule containing endospores 2 to 5 µm in diameter. Pathogenesis

Primary infection occurs in the lungs. Neutrophils, lymphocytes, and monocytes influence fungal dimorphism toward the spherule phase. A fungal enzyme with elastase activity may facilitate the spread of infection and increase inflammation.[5] *C. posadasii* perturbs pulmonary surfactant proteins, potentially enabling disease progression.[6] Molecular techniques have been used to examine (1) specific genes that affect virulence and (2) a cell surface glycoprotein that is produced early in spherule development, acts as an adhesin, and has been found to be a major contributor to pathogenicity.[7] An initial neutrophilic inflammatory response does not control infection despite rapid phagocytosis of *Coccidioides* particles,[8] and granulomatous inflammation eventually predominates. A characteristic histologic finding is granulomatous inflammation containing spherules and endospores (see Fig. 253.2).

Primary pulmonary infection, whether clinically apparent or asymptomatic, often is accompanied by dissemination of the fungus. Symptoms of extrapulmonary infection occur in about 1% of infected patients, and virtually any organ system can be involved, although the central nervous system (CNS), skin, and bone are most often affected in cases of disseminated infection.

Immunity

Despite complement-dependent chemotaxis induced by fungal elements, neutrophils and macrophages have a diminished capacity to kill *Coccidioides* forms intracellularly. Phagocytosis of spherules is physically difficult because of the size of these forms (≤80 μm).[8] A metalloproteinase produced during endosporulation interferes with host recognition, thereby impairing phagocytosis when these fungal elements are most susceptible.[9] Fibrillar surface matrices also prevent effective leukocyte contact with spherules and isolate endospores from phagocytic fungicidal mechanisms.[10]

Natural infection results in lifelong immunity. Polyclonal B-lymphocyte activation and increased serum complement fixation (CF) antibody titers develop in cases of severe infection, especially when coupled with loss of skin test reactivity, but humoral immunity is not completely protective. Protection has been firmly related to induction of Th1-associated immune responses. Coccidioidal antigens are processed and presented to T lymphocytes by macrophages and dendritic cells. This induces the production of interferon γ (IFNγ) and other Th1 cytokines that act by recruiting and activating immune effector cells.[11] Stimulated coccidioidal-immune T lymphocytes interact with and activate macrophages and enhance phagosome-lysosome fusion and killing. A diminished Th1 response to *C. immitis* antigens has been demonstrated in patients with disseminated infections, compared with Th1 responses in otherwise healthy subjects.[12] A variety of factors may contribute to this weaker response, including high concentrations of fungal antigen, circulating immune complexes, and direct suppression of immunity by fungal products or effectors.[13] Congenital or acquired impairment of cellular immunity is a major risk factor for serious primary infection or relapse of past infection.

Epidemiology

Coccidioidomycosis occurs in arid regions of the southwestern United States and is endemic to southern California, Washington, Utah, Arizona, western and southern Texas, and New Mexico (Fig. 253.3).[2] Infection also occurs in regions of Mexico and Central and South America where biogeographic distribution probably resulted from a codispersal of the human host population and its pathogen. Environments with hot summers, infrequent freezes, alkaline soil, and alternating periods of rain and drought support fungal growth and aerosolization of arthroconidia. Analyses of epidemic strains have shown that outbreaks result from environmental distribution rather than from the emergence of a pathogenic subtype.[14,15]

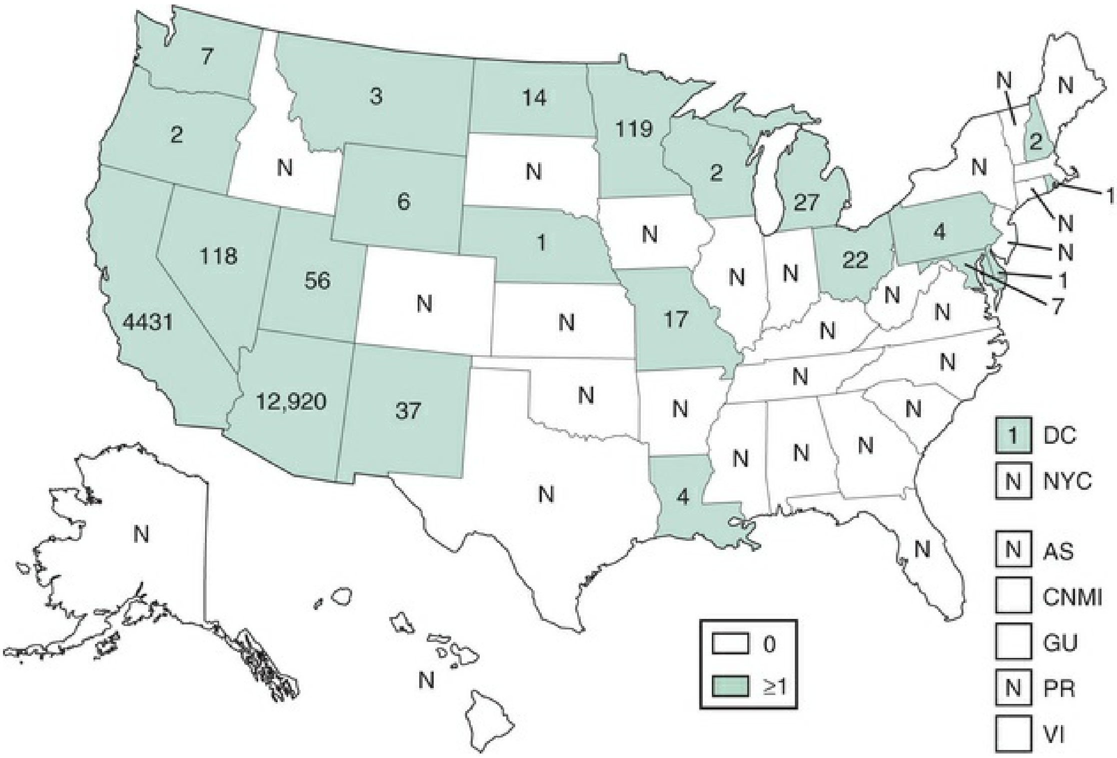

FIGURE 253.3 Coccidioidomycosis reported cases: United States and U.S. territories, 2012. N, not

notifiable; DC, Washington, DC; NYC, New York City; AS, American Samoa; CNMI, Commonwealth of the Northern Mariana Islands; GU, Guam; PR, Puerto Rico; VI, Virgin Islands. (Data from Centers for Disease Control and Prevention. Summary of notifiable diseases: United States, 2012. MMWR Morb Mortal Wkly Rep 2014;61[No. 53]:58.)

Infection usually is acquired during recreational or occupational activities that increase the likelihood of exposure to aerosolized arthroconidia. Examples of such activities include construction work, military exercises, archeological investigations, and recreational events. Outbreaks also can happen after earthquakes, such as occurred in 1994 after the Northridge earthquake.[2] A fourfold increase in the incidence of infections was seen in both Arizona and California between 2000 and 2007.[2] Infections can be difficult to diagnose when a traveler returns to a nonendemic area where practitioners have little experience with the diagnosis and care of coccidioidomycosis. Outbreaks also have occurred among travelers returning from regions not previously known to be endemic.[16] Fomites, such as dusty clothing or agricultural products, also have been implicated as sources of infection and may account for cases well outside the established endemic region.[17,18] Person-to-person spread of coccidioidomycosis has not been documented by the respiratory route; however, bandages contaminated by purulent drainage on which arthroconidia had grown have been implicated in transmission.[18]

An estimated 150,000 new infections occur annually in the U.S.[19] Rates are highest in the fall and early winter. Coccidioidomycosis has become increasingly important as migration to the Sunbelt states (and accompanying construction) has grown, as have the numbers of elderly and immunosuppressed people in the endemic region.[2] Skin test positivity was found in 17% of children who had lived in a highly endemic area for up to 1 year and in 77% of those who had lived in an endemic area for 10 years or longer. The return of skin testing reagents (Spherusol) to the commercial market has allowed the epidemiology of coccidioidomycosis to be updated.[20,21]

Clinical Manifestations

Infection is subclinical in roughly 60% of those exposed, and most other cases are self-limited, primary pulmonary infections. Of those infected, pulmonary complications occur in less than 5% and disseminated infections in less than 1%. Pulmonary complications and extrapulmonary infections can occur without recognized antecedent illness. In 2005 to 2006, illnesses in children that required hospitalization mirrored the increased incidence of disease in the general population; these illnesses also were more common among patients with comorbid conditions. Surgical drainage was required in 41% of the cases.[22]

Primary Pulmonary Infection

The incubation period is 10 to 16 days (range, 1–4 weeks). Malaise, chest pain, and fever are common symptoms.[3] Cough is variable, and hemoptysis is unusual in children. An acute, diffuse, erythematous rash and erythema multiforme are common. Erythema nodosum and fever can follow the onset of symptoms by 3 to 18 days. Erythema nodosum and transient arthritic complaints (desert rheumatism) are mediated by the cellular immune response. Occasionally, pulmonary symptoms are absent and only hypersensitivity manifestations occur.[23]

Symptoms usually improve without treatment in a few weeks to several months. In adults 5% to 10% of infections result in residual pulmonary nodules or thin-walled cavities, and patient education in these circumstances is paramount to avoid an inappropriate oncologic workup in the future.[24] In rare cases primary pulmonary infections that result from exposure to large inocula are severe and progress to involve multiple areas of the lungs; they also can cause symptoms of adult respiratory distress syndrome.[3]

Chronic Pulmonary Complications

Chronic pulmonary complications are uncommon in children and usually occur in adults with diabetes mellitus or an immunocompromising condition. Chronic progressive pneumonia, lung cavities, and pulmonary nodules are the most common manifestations (Fig. 253.4). Peripheral thin-walled cavities sometimes rupture into the pleural space and cause pyopneumothoraces.

Extrapulmonary Manifestations (Dissemination)

Clinical manifestations of dissemination to extrapulmonary sites occur in about 0.5% to 1% of patients, usually within several months of the primary pulmonary infection and rarely after 1 year. Dissemination is less frequent in children than in adults.[24] Persistent fever is common, and frequently affected sites include the skin, bones, joints, and CNS.[25] Those at highest risk are neonates and young infants, immunosuppressed patients, Filipinos, African Americans,[26] Native Americans, pregnant women, and women in the early postpartum period. Patients receiving tumor necrosis factor-α (TNF-α) antagonists[27] also are at risk (Box 253.1).

Osteomyelitis and Arthritis.

Osteomyelitis is subacute or chronic, and it occasionally is associated with extension into adjacent soft tissues.[28] Common sites are the hands and feet, ribs, skull, and vertebrae. Vertebral involvement can result in collapse, instability, paraspinal abscess or,[29] in some instances, meningitis. Monoarticular arthritis, often of the knee or ankle, occurs in 20% of adults with disseminated infection and can be chronic. Isolated osseous lesions can resemble neoplasms.[30]

Cutaneous Disease.

Most skin infections represent extrapulmonary manifestations caused by bloodstream spread from a primary pulmonary focus. Lesions begin as papules or pustules that enlarge and can ulcerate. Verrucous plaques, subcutaneous cold abscesses, and wart-like lesions also occur (Fig. 253.5). Lesions can occur anywhere but are common on the face. Cutaneous lesions accompanied by regional adenitis rarely occur after accidental inoculation.[31,32]

Meningitis.

Meningitis can occur acutely but often is subacute with transient periods of remission. Symptoms often include headache, altered sensorium, ataxia, vomiting, and focal neurologic deficits. Fever is variable, and meningismus occurs in only 50% of patients.[33] CNS vasculitis, often associated with cerebral infarction, is recognized increasingly; a retrospective review reported a mortality rate of 70%.[34] Basilar meningeal reaction can interfere with cerebrospinal fluid (CSF) resorption and cause obstructive or communicating hydrocephalus. If left untreated, meningitis is fatal within 1 to 2 years. Lifelong therapy is required to prevent relapse.[35]

Diagnosis

Symptoms of coccidioidomycosis are protean. A careful history of travel to endemic areas and inquiry about high-risk activities often prompts consideration of the diagnosis, particularly for patients living in nonendemic regions.[16,36]

Nonspecific Tests

The erythrocyte sedimentation rate usually is increased, and mild peripheral eosinophilia occurs in 5% to 10% of patients with primary infection. The chest radiograph can be normal or can show parenchymal infiltrates, hilar lymphadenopathy, thin-walled cavities, or parapneumonic effusion.[3] In patients with meningitis, the CSF shows pleocytosis with a predominance of lymphocytes or neutrophils, moderate hypoglycorrhachia, and an elevated protein concentration; eosinophilia is reported in 15% of cases.[33,37] Specific antibody is present in the CSF of patients with meningitis. Osseous lesions usually are lytic, but CT scans and MRI are more sensitive than plain radiography.[38] MRI is useful for demonstrating the bone marrow signal abnormalities of osteomyelitis and sites of decompression into soft tissue or joints.

Direct Examination and Culture

Observation of spherules containing endospores 2 to 5 µm in diameter is diagnostic. Spherules do not take up Gram stain but can be identified in infected body fluids with potassium hydroxide preparations or the calcofluor white stain. Stains of infected CSF usually are negative. In tissue samples, pyogranulomatous inflammation with endosporulating spherules is seen readily with hematoxylin and eosin stain or periodic acid-Schiff stain. Spherules also stain well with Gomori methenamine silver nitrate (see Fig. 253.2). Mold forms are rarely seen in body fluid or tissue specimens and typically only in the presence of foreign material (e.g., ventriculoperitoneal shunts).[39]

If organisms are not visualized in body fluid specimens or tissue, the diagnosis can be confirmed by culture. The mold form is a hazard to laboratory personnel; therefore, the clinical laboratory should be informed if coccidioidomycosis is suspected. The growth of *Coccidioides* spp. is supported by many conventional laboratory media at either 30°C or 37°C. Yield from respiratory tract secretions can be enhanced by chemical digestion of purulent specimens, and polymerase chain reaction protocols have been developed for direct detection in sputum samples.[40] Cultures of blood infrequently are positive except in highly immunocompromised people with disseminated infection. Culture of purulent material from other infected sites can be positive, although urine, peritoneal fluid, and CSF cultures are often negative despite infection at these sites. The fungus is isolated in culture in its mycelial phase and can be confirmed as *Coccidioides* spp. using exoantigens or nucleic acid probes.[41] Progress in development of molecular diagnostic techniques that can identify *Coccidioides* spp. in clinical specimens has been reviewed.[42] Polymerase chain reaction testing in a clinical setting has been shown to identify negative results accurately with a sensitivity similar to that of fungal culture.[40]

Skin Test

Four weeks after exposure, almost all infected individuals have a positive intradermal skin test result (induration ≥5 mm) to coccidioidal antigen prepared from spherule forms (Spherulin).[43] Although recent conversion of skin test reactivity is diagnostic, reactivity persists after infection, which relegates the skin test to use primarily as an epidemiologic tool. Cutaneous anergy in infected, symptomatic patients suggests the presence of a poor immunologic response and is a poor prognostic sign.[44] Conversely, conversion to skin test positivity correlates with improvement. The return of skin testing in a new formulation (Spherusol) has renewed interest in this test.[21]

Serologic Tests

Assays for coccidioidal antibody are valuable diagnostic and prognostic tools and are the mainstay of diagnosis and management.[45] False-negative test results can occur early in the course of infection, before the development of an immune response, and in highly compromised people, who are unable to manifest a robust antibody response. Cross-reactions with *Histoplasma capsulatum, Blastomyces dermatitidis,* and *Talaromyces marneffei* (formerly *Penicillium marneffei*) can occur in some assays.[46,47]

The use of enzyme immunoassay (EIA) kits for antibody detection is associated with false-positive test results but is useful for screening when followed up with a more specific assay. Circulating antigen is detected in patients with extensively disseminated infection and also in sequestered sites (e.g., CSF), but this finding is not useful in the routine management of most patients. Antigen detection also can result in cross-reaction with other endemic mycoses.

Specific IgM anti-*Coccidioides* antibody is detectable in 75% of patients 1 to 3 weeks after the onset of symptoms and is usually absent after 6 to 9 months. IgM historically was detected by the tube precipitin test, but current methodologies use the more sensitive immunodiffusion tube precipitin (IDTP) technique. Latex particle and EIA methods also are available as screening tests for IgM anti-*Coccidioides* antibody, but positive results should be confirmed using more specific methods.[48]

The CF assay detects IgG-specific antibody; it is positive in about 50% of patients at 4 weeks and in 83% at 3 months after infection. CF titers become undetectable within several months if the infection resolves, although a small minority of patients appear to be serofast. CF titers greater than 1 : 16 correlate with the presence and severity of disease. A quantitative immunodiffusion complement fixation (IDCF) test for detecting IgG antibody also is available and should not be confused with the IDTP test. The IDCF method is useful for sera that are anticomplementary.

Coccidioidal antibody is present in the CSF of 95% of patients with coccidioidal meningitis, although serial samples may be required. Titers decline during effective therapy. A parameningeal focus of coccidioidal infection also can cause a positive CF result in cerebrospinal fluid.

Treatment

The decision to treat is based on specific features and the severity of the initial illness, risk factors for severe infection or poor outcomes, or both[24] (see Box 253.1). Treatment is required for patients with primary or acquired immunodeficiency, including those receiving TNF-α blocking agents, and for patients with fulminant infections, extrapulmonary manifestations, or prolonged symptoms. In an observational study of patients with primary pulmonary coccidioidomycosis, complications of infections were observed only in those who initially received antifungal therapy. This was not a randomized controlled trial, but it does illustrate that complicated disease or dissemination can develop even in those treated for the initial infection.[49]

Published reports of the results of amphotericin B treatment (the first antifungal agent used) are limited to nonrandomized, open-label studies of chronic pulmonary infections and extrapulmonary disease. Accumulated experience with intrathecal and intracisternal instillation of amphotericin B for the treatment of meningitis also has been reported.[50] Because of the toxicity and inconvenience of amphotericin B, use of alternative agents has become desirable, and the effectiveness and relative safety and convenience of the oral azoles are now very attractive. Amphotericin B generally is reserved for use in the management of severe or rapidly progressive disease. Amphotericin B also is used for women during pregnancy because the azole agents have the potential for teratogenicity.[51] Some experts reserve amphotericin for use as salvage therapy.[52] No clinical evidence supports greater efficacy of lipid formulations of amphotericin B; however, the lower rate of nephrotoxicity observed with lipid formulations provides a substantial advantage over amphotericin B deoxycholate.

Fluconazole and itraconazole are the principal agents used for treatment.[24] Selection of an azole is based on proven efficacy for the disease manifestation, tolerability, and cost.[53] Although better tolerated than amphotericin B, these agents also have adverse effects, pharmacokinetic properties, and drug interactions that must be considered (see Chapter 293). Voriconazole and posaconazole have shown efficacy in the treatment of coccidioidomycosis,[54–56] although their use is limited to patients with chronic or disseminated infection who are intolerant of or refractory to first-line agents. Recommendations for children are derived from published experience in adults; however, extrapolation of treatment and outcomes disregards the potential differences in host factors and tolerance of therapy. Physicians who treat children with coccidioidomycosis should consider seeking consultation with experts.

Primary Infection

Immunocompetent patients without risk factors (see Box 253.1) who have mild respiratory symptoms usually do not require treatment. However, they should be assessed at 3- to 6-month intervals for up to 2 years to ensure that both symptoms and radiographic abnormalities have resolved.[24] Severe, prolonged, or progressive primary respiratory tract infections require antifungal therapy. Firm criteria for severity have not been established yet for children; useful indicators in adults include loss of more than 10% of body weight; symptoms that persist for 3 weeks or longer; pulmonary infiltrates that involve more than one half of one lung or that occur bilaterally; prominent hilar lymphadenopathy; chest pain; and CF titers of 1 : 16 or higher.

Itraconazole or fluconazole is used most often for the treatment of primary infection. The duration of treatment typically is 3 to 6 months. Important determinants of improvement include resolution of respiratory and constitutional symptoms, a decrease in CF antibody titers, and radiographic improvement. Periodic reassessment is needed for at least 1 to 2 years thereafter. Patients with pulmonary infiltrates should be followed to resolution, or as a pulmonary nodule forms so that the knowledge avoids a later oncologic evaluation.

Nonmeningeal Extrapulmonary Infection

Treatment is indicated for all extrapulmonary infections and in all immunocompromised patients, including pregnant women.[24] In patients with severe illness or rapid progression of disease, amphotericin B formulations are used initially. The dose and duration of amphotericin B therapy depend on the severity of the symptoms, rapidity of response, and host-related risk factors. The remainder of the course of treatment can be completed with an oral azole, except during pregnancy, when amphotericin should be continued. The total duration of therapy should be at least 1 year and should extend for 3 months beyond complete resolution of symptoms. Because late relapse can occur, usually within 2 years of apparently successful treatment, long-term follow-up is required. Treatment for meningitis and spinal disease should be lifelong.

The azole agents have been evaluated in the treatment of extrapulmonary manifestations of coccidioidomycosis in adults. Fluconazole (800–1200 mg/day)[57–60] and itraconazole[61,62] (200 mg twice daily) are effective and have been compared in a randomized trial.[63] The primary endpoint did not show superiority of either compound, but itraconazole showed more favorable outcomes in patients with osseous disease. Relapse rates after cessation of a 12-month course of therapy were 18% for itraconazole and 28% for fluconazole (a difference not statistically significant). The dose range for itraconazole in children is 5 to 10 mg/kg/day; the suspension form is better absorbed and is preferred (adult dose, 100–200 mg twice daily).

Meningeal Infection

Amphotericin B, given both systemically and either intrathecally or directly instilled into the cerebral ventricles or cisterna magna,[50] was the mainstay of therapy for coccidioidal meningitis before the azoles became available. The inconvenience and toxic effects of amphotericin, in addition to the irritating arachnoiditis resulting from intrathecal instillation, have relegated amphotericin formulations to second-line therapy (i.e., used only if the response to an azole is suboptimal). Fluconazole shows favorable CSF pharmacokinetics for CNS disease. Doses effective in adults are 400 mg/day, but some experts begin therapy with 800 to 1000 mg/day and increase as tolerated by the patient.[33] Response rates to fluconazole range from 67% to 80%. Children should be treated with fluconazole at doses in the upper end of the recommended range (12 mg/kg/day).[64] Indicators of improvement are a reduction in the CSF cell count and protein level and a decrease in the CF titer of the cerebrospinal fluid.

Despite excellent response rates to azoles, relapse of infection after the cessation of therapy was reported in 14 of 18 patients treated with an azole.[65] Relapses occurred 2 weeks to 30 months after the cessation of treatment courses that lasted 8 to 101 months. Because no clinical or laboratory factors predictive of relapse have been identified yet, fluconazole therapy should be continued indefinitely.

Patients who fail to respond to treatment with an azole may improve with systemic therapy and direct instillation of amphotericin B into the intrathecal, ventricular, or intracisternal spaces, with or without continuation of azole treatment. The optimal management of CNS vasculitis is unclear.

The persistent basilar inflammation resulting from meningitis caused by *Coccidioides* can result in obstructive hydrocephalus, necessitating placement of a CSF shunting device. In these cases, the abnormal dynamics of CSF flow interferes with the distribution of intrathecally administered amphotericin B; fluconazole, which crosses the blood-brain barrier more readily, simplifies the management of such patients. The development of hydrocephalus is not necessarily indicative of treatment failure and does not itself require any alteration in antifungal management unless it is accompanied by other findings suggestive of treatment failure.

Special Considerations

Acquired or inherited cellular immune dysfunction is a risk factor for aggressive and disseminated coccidioidomycosis. In this setting diagnosis often rests on clinical suspicion, histopathologic findings, and culture. Skin test anergy and seronegativity do not exclude the diagnosis in an immunocompromised person. Although the incidence of coccidioidomycosis is highest in residents of endemic areas, infections can occur in residents of nonendemic areas[36] as a result of exposure during travel or from recrudescence of past infection. HIV-positive patients are at high risk for active coccidioidomycosis if the CD4$^+$ lymphocyte count is lower than 250/mm^3.[66,67] People with no apparent symptoms of active infection but who have elevated coccidioidal antibody titers also are at risk for having active coccidioidomycosis. Treatment strategies are similar to those for patients who are not immunocompromised; they include amphotericin B for severe or diffuse pulmonary disease, then fluconazole or itraconazole. For mild disease monotherapy with fluconazole or itraconazole is recommended. After treatment, if immune reconstitution is not possible, lifelong antifungal suppression with fluconazole or itraconazole is needed to prevent relapse.[67]

Recrudescence of coccidioidomycosis is common in patients who receive organ or hematopoietic stem cell transplants.[68] Seropositive transplant recipients and/or people with previous clinical coccidioidomycosis should receive prophylactic antifungal therapy, and fluconazole has been used successfully for this purpose.[69,70] Severe coccidioidomycosis has been reported in recipients of organs from donors with unrecognized infections. In these instances diagnosis can be delayed if transplantation is performed in nonendemic regions using organs procured from patients from endemic areas.[71]

Limited clinical information is available for newer therapeutic agents. Posaconazole, an extended spectrum triazole with activity against *Coccidioides* spp., has been shown to be effective in patients with pulmonary and disseminated infection, and despite the absence of detectable CSF levels, it has shown efficacy in the treatment of meningitis. Similarly, voriconazole has been proven effective in the treatment of pulmonary, disseminated, and meningeal forms of coccidioidomycosis.[55,56] These agents currently have limited use, primarily because of cost concerns.

The echinocandins should not be used as monotherapy in the treatment of coccidioidomycosis because of a lack of inherent activity. However, echinocandins used in combination with other agents can be useful in the salvage setting. This “indirect” efficacy is likely a product of an immunopharmacologic mechanism, as is seen in the treatment of other fungi.[72]

Prevention

Substantial evidence supports the feasibility and usefulness of an effective vaccine for coccidioidomycosis.[73] Attempts to immunize with a killed spherule vaccine were unsuccessful, and candidate immunizing agents and approaches remain under development. Primary prophylaxis with an azole is not recommended for patients with HIV infection, although secondary prophylaxis may be indicated in recipients of solid-organ or bone marrow transplants who have a history of coccidioidomycosis or positive skin tests/serologic testing. In endemic areas exposure to activities that may aerosolize spores in heavily contaminated sites should be avoided, especially by immunosuppressed people. If such an activity is unavoidable, respiratory filtration devices should be used.

Key Points

Coccidioides immitis and *Coccidioides posadasii*

Microbiology

- *Coccidioides* spp. are endemic, dimorphic fungi that exist as saprophytic molds in the environment and as endosporulating spherules in parasitic forms.
- Multinucleate spores (arthroconidia) released from the mold result in a primary respiratory tract infection after inhalation.
- Conversion to spherules in the host releases large numbers of endospores that amplify infection.

Epidemiology

- *C. immitis* is found in California and Washington state; *C. posadasii* is found primarily in Arizona, Mexico, and regions of Central and South America.

- Hot summers, alkaline soil, infrequent freezes, and alternating rain and drought favor growth.

- Isolated and epidemic outbreaks can result from activities and environmental conditions that favor fungal growth and aerosolization of spores.

Diagnosis

- Diagnosis is confirmed by culture or observation of endosporulating spherules in tissue specimens.

- In immunocompetent individuals, immunoglobulin M (IgM)–specific antibody is found in 75% within 1 to 3 weeks of symptom emergence; IgG-specific antibody is present in 50% by 4 weeks and in 83% by 3 months.

- Standardized complement fixation titers greater than 1 : 16 correlate with the presence and severity of extrapulmonary disease.

- Complement fixation antibody is present in the cerebrospinal fluid of 95% of patients with meningitis.

Treatment

- For all patients, follow-up is required for 2 years to ensure resolution.

- Antifungal therapy is required for severe, prolonged (>6 weeks) primary infection, all extrapulmonary infections, and in patients with risk factors for poor outcomes.

- Fluconazole and itraconazole are effective; itraconazole is preferred for bone infections; fluconazole achieves effective levels in cerebrospinal fluid and is preferred for central nervous system infections.

- Amphotericin B is preferred for severe, rapidly progressive, nonmeningeal infections; after induction, azole agents are used to complete therapy.
- Management of meningeal infections is complex, and consultation with experts is recommended.

Dermatophytes and Other Superficial Fungi

Tanya Greywal, Sheila Fallon Friedlander

Dermatophytes are aerobic fungi that can invade and infect keratinized layers of the skin, hair, and nails, mediated by both keratinases and proteases. Originally thought to derive from parasites transmitted from cats or dogs, infection was referred to as *tinea* (from the Latin word for worm), followed by a modifying term (e.g., *capitis*) that described the affected body site. Most dermatophyte infections involve three genera of fungi: *Trichophyton, Microsporum,* and *Epidermophyton*. These fungi are found worldwide; infection is acquired from contact with affected humans or animals, or from exposure to contaminated soil or fomites (e.g., combs, brushes). Dermatophytes often are classified by their host preferences—anthropophilic and zoophilic species primarily infect human and animal species, respectively, whereas geophilic species reside in soil. Direct contact can result in transmission of zoophilic or geophilic dermatophytes to humans. Dermatophytes do not cause invasive disease, except when they invade the dermis and subcutis locally (Majocchi granuloma) or infect immunocompromised hosts. The clinical disease attributed to dermatophytes varies by organism, site of infection, and host immunologic responses.

Tinea Capitis

Key Points

Diagnosis and Management of Tinea Capitis

Microbiology

- *Trichophyton tonsurans*, an anthropophilic dermatophyte, is the most common cause of tinea capitis in North America.
- Other causes: *Microsporum canis* (usually from pets), *Microsporum audouinii, Trichophyton mentagrophytes, Trichophyton violaceum*

Epidemiology

- Highest prevalence in children 3 to 10 years of age; family members at risk; can occur in postmenopausal child caretakers
- More common in urban settings
- *T. tonsurans* is transmitted from human to human.
- *M. canis* is transmitted from pets (dogs, cats).

Diagnosis

- Direct microscopy with KOH examination
- Fungal culture
- Wood light for *M. canis* and *M. audouinii*: fluoresce bright yellow

Treatment

- Oral griseofulvin (20–25 mg/kg/day, micronized, maximum dose of 1g) often used; should be taken with a fatty meal to increase drug absorption.
- Terbinafine is an FDA-approved alternative that often requires a shorter duration of therapy, but may be more expensive; see dosing in text.

- Second-line therapies: itraconazole or fluconazole
- Adjunctive antifungal shampoo: selenium sulfide 2%, ketoconazole, or ciclopirox; twice a week use decreases infectivity

Duration of Therapy

- For griseofulvin, 6 to 8 weeks of therapy is recommended (with treatment 2 weeks beyond clinical resolution of disease).
- For other agents, shorter courses can be used (e.g., terbinafine, 5–8 mg/kg/day for 4 weeks).

Microbiology and Epidemiology

Tinea capitis is the most common pediatric dermatophyte infection in temperate climates worldwide and is a common cause of hair loss in prepubertal children.[1] The precise incidence is unknown; however, infection is most common in younger elementary school-aged children, and it occasionally affects postpubertal individuals.[2,3] Prepubertal prevalence may relate to the absence of sebum fatty acids, which possess fungistatic properties.[4]

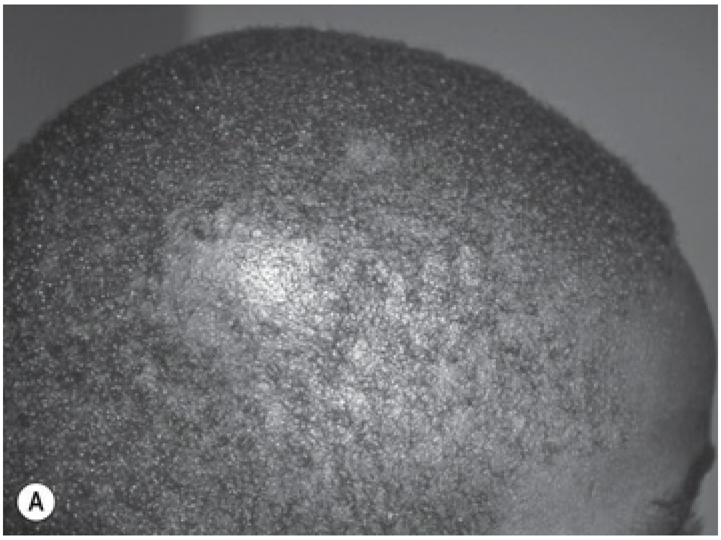
Prevalence and pathogens vary widely.[5] *Trichophyton tonsurans* is most common in the United States, whereas *Microsporum canis* is usually seen in South America and around the Mediterranean.[6] *Trichophyton soudanense* and *Trichophyton violaceum* are the major causes of disease in many parts of Africa and have also been found in immigrant populations in Scandinavia and other European countries.[6]

T. tonsurans is the predominant cause of tinea capitis in North America and Central America, accounting for >90% of cases.[7] In a survey of elementary school-aged children in Alabama, the incidence of *T. tonsurans*–positive scalp cultures was approximately 11%, with symptomatic disease in only 3%. In another study of >10,000 US children, approximately 6% were culture positive.[8,9] However, a retrospective study using the International Classification of Diseases, ninth revision codes for symptomatic tinea capitis identified a much lower rate of infection (0.1%).[10]

T. tonsurans is transmitted from human to human, whereas animals are the typical vectors of *M. canis*. Of note, *M. canis*, *Microsporum audouinii, Trichophyton mentagrophytes,* and *T. violaceum* less frequently cause infection in North America. Overall, these infections can be insidious, with frequently asymptomatic scalp colonization in endemic regions. *T. tonsurans* often is isolated from symptom-free family members of infected individuals, who play an important role in the spread of infection.[11,12] One small study found that siblings had a 46% risk for infection, owing to reservoirs such as shared hair brushes and combs.[13] There is no evidence that hair care practices (e.g., use of pomades, braiding) facilitate infection. There have been recent outbreaks of *T. tonsurans* infection in group childcare, which can last several months and are difficult to clear.[14]

Clinical Manifestations

Tinea capitis can present with myriad findings—from a spectrum of subtle, almost imperceptible diffuse hair loss to severe boggy, scaling abscess-like nodules. The more common findings include patchy areas of scaling and hair loss (Fig. 254.1). Involved areas can show scattered broken hairs of various lengths or areas of discrete hair loss with broken stubs of hair (black dot ringworm). Occipital or posterior cervical lymphadenopathy is a clue to diagnosis.[15]



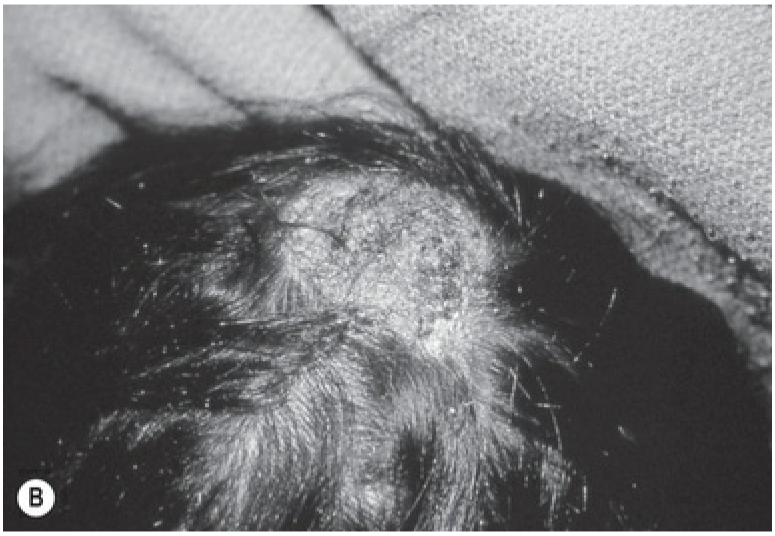


FIGURE 254.1 (A) Tinea capitis. Note the focal alopecia and scaling. (B) Kerion associated with tinea capitis from Trichophyton tonsurans.

In more severe inflammatory disease, a boggy, indurated mass, often with superimposed vesicles and pustules, can be present (Fig. 254.2). Known as *kerion celsi,* the lesion represents an extreme local immunologic response to infection.[16] When associated with fever, lymphadenopathy, leukocytosis, and purulent drainage, a kerion can be misdiagnosed as a bacterial infection or abscess, and the patient might be exposed to unnecessary surgical procedures or antibiotic therapy.[17] In addition, patients can have a dermatophytid ("id") immunologic response to dermatophytosis, which is characterized by pruritic, papulovesicular, or eczematous eruptions involving the face, trunk, or extremities.[18] This eruption, which sometimes occurs following initiation of therapy, is a hypersensitivity response to the infecting fungus and should not be confused with a drug reaction.

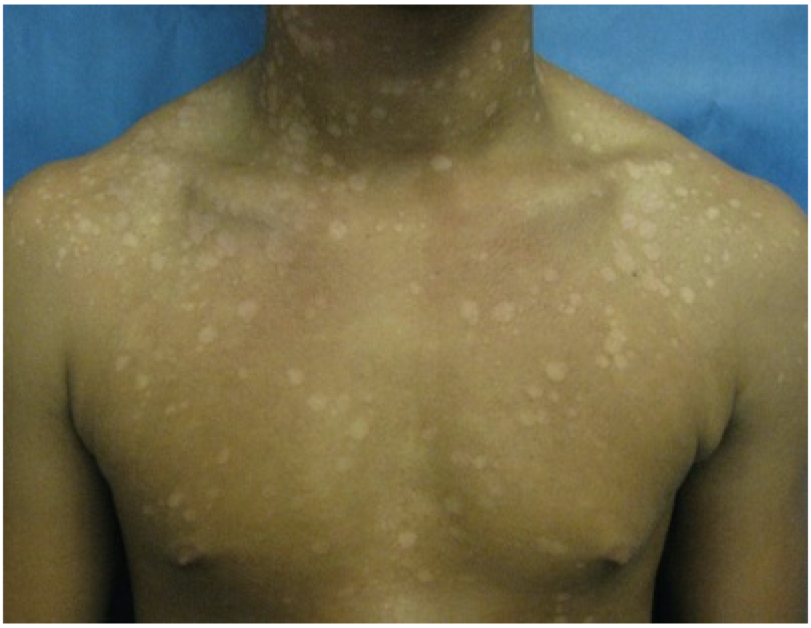

FIGURE 254.2 Tinea versicolor. Hypopigmented patches with fine scale.

Tinea capitis should be suspected in any prepubescent child with unexplained hair loss, particularly if the hair loss is focal, patchy, and accompanied by scaling or lymphadenopathy. Although a presumptive diagnosis can be made clinically, confirmation should be attempted whenever possible. Wood light examination of the area of hair loss can establish the presence of a *M. canis* or *M. audouinii* infection. Because these dermatophytes invade the outer hair shaft (ectothrix), they will fluoresce yellowish-green when exposed to ultraviolet light. By contrast, the more common *T. tonsurans* invades the inner core (endothrix) of the hair shaft and cannot be detected using ultraviolet light. Potassium hydroxide (KOH) preparation of affected hairs or scale and culture are standard evaluations. Samples are obtained by scraping or plucking hair in the affected area, followed by a KOH examination that may reveal arthroconidia or spores within or around the hair shaft, or hyphae. A specimen for culture is obtained by rubbing a moistened cotton-tipped applicator or toothbrush over the involved scalp and then placing the sample in a culturette transport system.[19] Family members should be queried regarding symptoms, and many experts recommend treating all family members empirically with twice-weekly topical ketoconazole or selenium sulfide antifungal shampoo.

The differential diagnosis for tinea capitis includes alopecia areata, atopic dermatitis, folliculitis, impetigo, lupus erythematosus, psoriasis, seborrheic dermatitis, traction alopecia, and trichotillomania.[20] Alopecia areata usually manifests as focal hair loss without inflammation or scaling; careful examination often reveals the presence of exclamation point hairs, which are broader at the tip of the hair with a diminution in the diameter of the hair closest to the scalp. Fractured hairs of different length, unusual patterns of hair loss, and excoriations of the scalp are hallmarks of trichotillomania; patchy hair loss of eyebrows and eyelashes also is seen more commonly in both trichotillomania and alopecia areata than in dermatophytosis. Seborrheic dermatitis, atopic dermatitis, and psoriasis typically are not associated with alopecia, although scratching can cause secondary scalp and hair changes that mimic tinea capitis.

Treatment

Standard treatment previously consisted of griseofulvin, 20 mg/kg daily (maximum of 1 g) in micronized form (available in suspension), or 10 to 15 mg/kg daily (maximum of 750 mg) in ultramicronized form. Because it is frequently the only agent covered by insurance plans, griseofulvin remains a popular, widely used treatment. The duration of treatment generally is 6 to 8 weeks. In recent years, many providers have found that higher doses of micronized griseofulvin (up to 25 mg/kg daily) and longer durations of treatment are sometimes required for cure.[21] *M. canis* disease often is more difficult to treat than *T. tonsurans*, and higher dose and longer duration of therapy often are required to achieve complete resolution.[22,23] Administration of griseofulvin with a fatty meal (e.g., milk, ice cream, peanut butter) enhances drug absorption; laboratory tests to monitor for adverse effects are not required unless therapy exceeds 8 weeks. A prospective trial using micronized griseofulvin (20 mg/kg/day) and topical therapy with twice-weekly selenium sulfide shampoo for 6 weeks showed mycologic, clinical, and complete cure rates of 89%, 66%, and 49%, respectively.[24] Common side effects of griseofulvin include nausea, headache, and photosensitivity reactions.

Many experts now consider terbinafine the better option for treating *T. tonsurans*. Terbinafine was approved by the US Food and

Drug Administration (FDA) for children, and because a 2- to 4-week course can results in cure, adherence is more likely.[25] A large, multinational randomized controlled trial of >1500 children compared oral griseofulvin (10–20 mg/kg/day) with terbinafine oral granules (5–8 mg/kg/day) for 4 weeks.[26] Complete clinical and mycologic cure was significantly higher in those treated with terbinafine, particularly for *T. tonsurans* infections.[26] Other studies have shown high cure rates with 2-week courses of terbinafine using a weight-based sliding scale dosing system with standard 250-mg terbinafine tablets: ¼ tablet (62.5 mg) to ½ tablet (125 mg) for patients weighing 20 to 40 kg, and 1 full tablet (250 mg) for patients >40 kg.[27] For *Microsporum* spp. and other inflammatory *Trichophyton* spp. infections, griseofulvin is superior to terbafine.[28,29] When choosing treatment, one must keep in mind that *T. tonsurans* accounts for more than 90% of US scalp infections.

Treatment with oral fluconazole or itraconazole, using daily or pulse regimens, can be effective for tinea capitis, and shorter duration of therapy also appears efficacious; however, limited data are available in children.[21,25,30] In addition, all of these agents, as well as terbinafine, rarely cause hepatic inflammation. Therefore most experts recommend obtaining baseline measurements of serum hepatic enzymes, with repeat testing if clinical symptoms or signs suggest possible hepatotoxicity.

In conjunction with oral therapy, topical agents such as selenium sulfide shampoo (1% or 2.5%), ciclopirox shampoo (1%), and ketoconazole shampoo may reduce the number of surface fungi and thus overall infectivity. A study comparing selenium sulfide shampoo 1% and ciclopirox shampoo 1% as adjunctive agents showed equivalency.[31] Topical therapies alone are not sufficient for treatment.[5,31–33]

Other therapies such as systemic corticosteroid, antibiotic, or surgery generally are not indicated.[34–37] Studies of use of systemic corticosteroids do not show consistent benefit for accelerated healing or reduction of postinflammatory scarring.[34–36] Nonetheless, in cases of severe inflammation that do not respond rapidly to systemic antifungal therapy, many experts use a short (10–14 day) course of oral prednisone in an effort to decrease scarring.

Tinea Pedis (Athlete's Foot)

Microbiology and Clinical Manifestations

Tinea pedis is a superficial fungal infection of the epidermis commonly caused by *Trichophyton mentagrophytes* var. *interdigitale, T. rubrum, Epidermophyton floccosum*, or *T. tonsurans*.[38] Infection is spread by contact with arthrospores from infected individuals, which can be present in pool, locker room, or bathroom areas. Tinea pedis is less common in prepubertal individuals, but some studies have reported prevalence of 2% to 4% in school-aged children.[39] Data from a human volunteer study suggest that the fungi responsible for tinea pedis do not invade normal skin.[40] A moist environment and maceration of the skin appear to be important predisposing factors. The role of bacteria in tinea pedis is poorly defined; however, some evidence indicates that subclinical bacterial infection may permit pathogenic fungi to invade the cornified epithelium.

There are three clinical forms of tinea pedis in children. The most common form is due to a variety of dermatophyte infections, including *T. rubrum*, and manifests as maceration, peeling, and fissuring of the intertriginous areas of the toes. Pruritus is the most prominent symptom. The second form of tinea pedis is due to *T. mentagrophytes* and manifests as vesicles, small bullae, and occasionally erosions, particularly on the instep of the plantar surface of the foot and interdigital web spaces. This inflammatory condition is subacute and can be associated with an eczematous rash or vesicles on the hands (*dermatophytid* or *id reaction*). In general, as the lesions heal, plaques and scales form. The third and probably least common form is usually caused by *T. rubrum* and is characterized by chronic, diffuse scaling and hyperkeratosis of the plantar surface of the feet and heels, referred to as *moccasin foot*.

Although some providers clinically diagnose and empirically treat patients, it is important to obtain KOH with or without cultures from children who have resistant or atypical disease. Common conditions mimicking tinea pedis in children include dyshydrosis, juvenile plantar dermatosis, allergic contact dermatitis, and irritant dermatitis. Occasionally, pitted keratolysis can be confused with tinea pedis, but pitted keratolysis is associated with a strong foul odor and usually manifests as small crateriform depressions of the soles and heels. In adolescents and adults, tinea pedis must be differentiated from bacterial infection, erythrasma, plaque or pustular psoriasis, and primary irritant dermatitis. Erythrasma can be diagnosed by using a Wood lamp that reveals a coral-red fluorescence; the axillae and groin are typically affected in erythrasma. Irritant and contact dermatitis generally spare the intertriginous areas of the toes. Also, the vesiculobullous form of tinea pedis can be confused with scabies or dyshidrosis.

Treatment

Topical antifungal agents are effective against most forms of tinea pedis. Common and effective topical agents include allylamines and imidazoles, including econazole, luliconazole, naftifine, and terbinafine.[41–45] A meta-analysis of 11 randomized trials comparing azoles with terbinafine and naftifine showed a slightly higher cure rate with terbinafine and naftifine.[46] Vesicular forms may benefit from wet compresses applied for short periods 2 to 3 times a day. Systemic therapy with griseofulvin or terbinafine may be necessary for treatment of a diffuse moccasin-foot type of infection. Alternatively, 40% urea cream in conjunction with a topical antifungal agent is thought to help loosen thick plantar scale, thus allowing increased absorption of the antifungal agent.[47,48]

Tinea Corporis (Ringworm)

Key Points

Diagnosis and Management of Tinea Corporis

Epidemiology

- 50% of cases in the US occur in children younger than 15 years.
- More commonly affects males than females
- Most infections result from human-to-human transmission.
- Outbreaks among wrestlers can occur, termed *tinea gladiatorum.*

Clinical Features

- Papulosquamous (most common): annular plaque with ring of scale and central clearing, classically termed “ringworm”
- Inflammatory or vesicular: plaques with vesicles at the advancing edge
- Granulomatous (Majocchi granuloma): nontender skin nodules with overlying crust, plaques; perifollicular distribution can occur
- Manifestations can be atypical (“tinea incognito”) if erroneously treated with topical corticosteroids.

Diagnosis

- Direct microscopy with KOH examination reveals hyphae; culture and biopsy with periodic acid–Schiff stain if necessary.

Treatment

- Topical triazoles: ketoconazole, clotrimazole or econazole once or twice a day
- Allylamines: terbinafine, naftifine
- Unresponsive cases, especially Majocchi granuloma, may require an adjunctive oral antifungal agent (e.g., fluconazole, griseofulvin, or terbinafine).

Duration of Therapy

- 14 to 21 days for topical therapy
- Duration of oral antifungal therapy depends on the agent chosen (e.g., ~2 weeks for fluconazole).

Microbiology and Clinical Manifestations

Tinea corporis is a superficial skin infection that occurs worldwide and affects all age groups. There is a predilection for males, and about 50% of cases in the US occur in children <15 years of age.[49] Any dermatophyte can cause disease, but the predominant pathogen varies geographically. *T. rubrum, T. tonsurans, T. mentagrophytes, M. canis*, and *E. floccosum* are the most common causes of tinea corporis in the US. Acquisition occurs through direct contact with infected humans or animals (primarily dogs and cats) and, less commonly, through exposure to contaminated fomites. The infectivity and inflammatory potential vary by species. Outbreaks among wrestlers are common and have been termed *tinea gladiatorum* (tinea capitis also can be present in affected individuals).[50] *T. tonsurans* is the most common cause of tinea gladiatorum in the US.[51]

Three clinical forms of disease occur: papulosquamous, inflammatory/vesicular, and granulomatous. Papulosquamous disease is the most common and manifests as an erythematous papule or plaque that evolves into an annular ring lesion with well-defined margins—the classic "ringworm." Infection spreads to involve surrounding healthy skin, often with a central area of clearing. Inflammatory or vesicular tinea corporis frequently occurs with *M. canis* infection and commonly has fine vesicular lesions at the plaque's advancing edge. Generally, remaining discrete lesions may coalesce. Granulomatous tinea corporis, often referred to as *Majocchi granuloma,* is the least common form of disease and often occurs in children whose initial infection was misdiagnosed and treated with topical corticosteroid agents, in immunocompromised hosts, or in females who have reinoculated the fungus while shaving their legs.[52] The granulomas form when dermatophytes within hair follicles rupture into the dermis and cause an inflammatory response. The infection is subacute or chronic and manifests as firm, nontender skin nodules with an overlying crust or plaque; lesions associated with leg shaving are follicular or perifollicular and often have a circumferential scale on an erythematous base.

Isolated lesions of nummular eczema can mimic tinea corporis, as can the herald patch of pityriasis rosea. Granuloma annulare and psoriasis often are mistaken for tinea corporis. If tinea corporis is erroneously treated with topical corticosteroids, the classical features of ringworm may not be evident. In such cases, the term *tinea incognito* is used, and KOH examination often aids in identifying the dermatophyte. Granuloma annulare can be mistaken for tinea corporis, and often is the true cause of "resistant tinea corporis." Granuloma annulare is distinguished by the absence of scale.

Diagnosis of *T. corporis* is optimized by making a KOH preparation from the active or leading edge scraping. Culture or biopsy with periodic acid–Schiff (PAS) staining is useful in equivocal cases.

Treatment

Most forms of tinea corporis can be treated with once- or twice-daily topical antifungal therapy for 14 to 21 days. Optimal duration of therapy and comparative efficacy of topical agents have not been evaluated extensively. Patients with widespread cutaneous lesions or a granulomatous reaction sometimes are treated systemically with terbinafine, griseofulvin, or alternative antifungal agents. Most recommend treatment with oral agents, and in a study using fluconazole 200 mg weekly, 100% of affected individuals were culture negative by the third week.[53] Several studies have documented a slight superiority and less side effects using newer agents, such as terbinafine and fluconazole, compared with griseofulvin.[54,55]

Tinea gladiatorum raises particular concern of spread to other athletes. It is unclear how long infected individuals should avoid contact with others, but many experts recommend 10 to 15 days after commencement of therapy.

Tinea Cruris (Jock Itch)

Tinea cruris is an acute or subacute superficial fungal infection of the perineum and groin that occurs primarily in males in warm, humid environments. There is an increasing incidence in postpubertal females who wear tight-fitting exercise garments or panty hose and in adolescents who are obese or diabetic.[56]

T. rubrum, T. mentagrophytes, and *E. floccosum* are the most common pathogens. The incidence of *T. rubrum* is increasing in the US.[7]

Tinea cruris typically manifests as red to reddish-brown, scaly lesions that usually are symmetric and have well-demarcated borders or fine, oozing vesicles or both. Local pruritus is a very common symptom. Chronically involved skin can manifest with brownish discoloration and well-defined borders.

The differential diagnosis includes allergic or irritant contact dermatitis, candida intertrigo, erythrasma (*Corynebacterium minutissimum* infection), psoriasis, and seborrheic dermatitis. Secondary infection with *Candida albicans* can develop in obese individuals with chronic tinea cruris. KOH examination of a specimen from the advancing edge of the lesion may show hyphae. Erythrasma can be identified and differentiated by its coral-red fluorescence when evaluated with a Wood lamp.

Treatment of tinea cruris depends on the clinical findings. Oozing areas should be treated with Burow solution compresses and the application of topical antifungal agents such as terbinafine, naftifine, and luliconazole.[57–59] For those with a *C. albicans* superinfection, the addition of nystatin powder is recommended because of its antifungal and drying properties. However, nystatin powder should not be mixed with the antifungal cream because this can form a gritty, irritating mixture. Also, when tinea cruris occurs with a concurrent dermatophyte infection of the fingernails or toenails (onychomycosis), treatment of both disorders may be required for cure.

Tinea Favosa

Tinea favosa (favus) is a chronic fungal infection of the scalp most commonly caused by *Trichophyton schoenleinii*. Tinea favosa does not occur in the US, except in recent immigrants or residents of a few well-localized, endemic areas. Favus generally is less contagious than other dermatophytoses, and intrafamilial infection is less prominent.[60]

Tinea favosa typically occurs in children and is classified into three clinical stages.[60] The first stage involves erythema of the scalp, with perifollicular involvement primarily. In the second stage, friable yellowish-brown crusts have a peculiar cup-shaped configuration (scutulum) and are associated with some hair loss. The last stage is most severe and affects large areas of the scalp with edema, oozing, focal ulceration, extensive hair loss, and eventually scarring alopecia. The differential diagnosis and treatment of tinea favosa are similar to tinea capitis.

Tinea Unguium (Onychomycosis)

Tinea unguium is a dermatophytic infection of the nails that is commonly associated with tinea pedis. Prevalence increases with age and is uncommon in prepubertal children. Worldwide prevalence ranges from 0.1% to 1%.[61] Adults have a higher prevalence at 2% to 14%, and prevalence in elderly people approaches 40%.[61] In addition, children with onychomycosis often have older affected family members.[62]

T. rubrum, T. mentagrophytes, and *E. floccosum* are the primary pathogens of tinea unguium.[63,64] Although clinical presentation can vary, most commonly the fungus directly invades keratin along the distal and lateral aspects of the nail and slowly spreads proximally along the nail.[39] The nail becomes "soft" and disfigured with subungual debris and nail discoloration. A more superficial infection creates focal, irregular opaque lesions on the nail.

Onychomycosis must be differentiated from congenital and acquired conditions that cause nail changes, such as alopecia areata, atopic dermatitis, bacterial infection, *Candida* infection, lichen planus, pachyonychia congenita, paronychia, psoriasis, trauma, twenty-nail dystrophy, and yellow nail syndrome.[65] *Candida* infection often has an associated paronychia and rarely causes subungual deposits. However, chronic mucocutaneous candidiasis should be considered in the differential diagnosis of any child with candidal onychomycosis.

Nail clippings and subungual debris should be obtained for diagnosis by direct microscopy and culture. Fungal elements can be visualized by direct microscopy of KOH-treated scrapings, but the sensitivity of this test is highly operator dependent.[66] A more reliable technique involves direct microscopic evaluation of paraffin-embedded nail clippings stained with PAS.[66] Relatively inexpensive, rapid PCR evaluation kits are now available at some research centers.

Treatment of onychomycosis includes oral and topical therapies. Griseofulvin is often used in children, but it has repeatedly been documented in adults that terbinafine leads to higher cure rates in onychomycosis than does griseofulvin. Most experts use terbinafine if financial and medical considerations do not contraindicate use. Alternatives therapies include itraconazole and fluconazole. The duration of griseofulvin therapy is prolonged (6–12 months), and recurrence is common. Terbinafine and the triazoles typically are administered for shorter durations (3 months) or as pulse regimens; however, they are not approved by the FDA for the treatment of pediatric onychomycosis.[62,67] In addition, mechanical debridement with 40% urea ointment applied daily for 10 days is sometimes used in cases recalcitrant to systemic therapy or when systemic therapy is contraindicated.

Classically, topical antifungal therapy has included ciclopirox and amorolfine. Newer agents that have been shown to be safe and effective include efinaconazole and tavaborole.[65,68–70] In general, topical agents also require a prolonged course of treatment (6–12 months) but may be less effective than oral medications because of inability to penetrate to the lowest portions of the nail bed. Therefore topical therapy generally is used only if there is no nail matrix (lunular) involvement. Young children have thin, fast-growing nails that may allow for enhanced drug penetration, and trials are underway to evaluate the new topical agents' efficacy in childhood disease.[71] Carbon dioxide laser treatment may increase penetration and efficacy in combination with topical antifungal therapy but has not proven to be highly efficacious.[72]

Tinea Versicolor (Pityriasis Versicolor)

Key Points

Epidemiology, Clinical Features, Diagnosis, and Treatment of Tinea Versicolor

Epidemiology

- Distributed throughout the US; more common in warm, humid climates

- Commonly affects adolescents and young adults.

Microbiology

- *Malassezia* (formerly *Pityrosporum)* spp. are causative organism; usually a benign commensal, but can assume an invasive form.

Clinical Features

- Often comes to medical attention during summer months with complaint of skin not tanning normally

- Pink, hypopigmented, or hyperpigmented patches and plaques with fine white scale

- Commonly distributed on neck, trunk, and proximal upper extremities; may occur on the face, particularly the temples, in young children

- Pruritus is minimal or absent.

Diagnosis

- Direct microscopy of KOH preparation shows spaghetti and meatballs appearance of blastoconidia and pseudomycelium; Wood lamp may show golden fluorescence.

- Modified Dixon agar or olive oil overlay on routine fungal media is used for culture.

Treatment and Duration of Therapy

- Topical antifungal cream and/or shampoo is generally sufficient treatment; should be used for at least 2 weeks; recurrence is common.

- Discoloration can persist for months despite clearance of infection.

- Oral antifungal agents (e.g., fluconazole, taken once and then repeated in 1 week) for resistant cases

Tinea versicolor is a common superficial yeast infection most frequently caused by *Malassezia furur* or *M. globosa. Malassezia* (formerly *Pityrosporum*) spp. are saphrophytic yeasts that are normal skin commensals in >90% of adults; however, under the right environmental circumstances, the dimorphic organism can invade the superficial epidermis and occasionally can cause invasive disease or sepsis in neonates and immunosuppressed individuals.[73] *Malassezia* thrives in environments rich in sebum and humidity and is therefore more common in older children and in tropical areas. Clinical findings include asymptomatic tan, pink, or hypopigmented macules or patches on the neck and upper trunk. Lesions often coalesce, leading to the presence of scalloped borders. Facial involvement, particularly on the temples, can be seen in children. Fine white (furfuraceous) scale may also be noted (Fig. 254.2). KOH preparation from skin scrapings reveals a spaghetti and meatball appearance of blastoconidia and pseudomycelium, confirming the diagnosis. Wood lamp examination reveals yellow fluorescence. Differential diagnosis includes pityriasis alba (particularly when occurring on the face), vitiligo, postinflammatory hypopigmentation, progressive macular hypomelanosis, tinea corporis, and, rarely, hypopigmented cutaneous T-cell lymphoma.

First-line therapy generally consists of topical imidazole or allylamine antifungal cream, particularly if involvement is localized to a small area. Unfortunately, involvement usually is more generalized, and antifungal shampoos, including ketoconazole and selenium sulfide, are often a cost-effective, simple way to treat larger areas. Ketoconazole shampoo can be applied in the shower and left on for a few minutes nightly for three consecutive nights, and then used monthly to help prevent recurrence. Patients should be advised that it may take months for the skin to repigment and that recurrence is common. Effective treatment of resistant or extensive cases includes oral fluconazole 400 mg in adolescents, given once and then repeated in 1 week.[74,75] Vigorous physical activity (causing sweating) within a few hours after taking the medicine increases penetration into the skin.[75] *Malassezia* (formerly *Pityrosporum*) spp. also can cause folliculitis, which is most concentrated in sebum-bearing areas (face, chest, back), and resembles acne but lacks comedones. It occurs most often in adolescents, particularly those who have been treated with long-term oral antibiotics, and in immunosuppressed patients. Oral antifungal agents are often required, although immunocompetent patients may respond adequately to topical antifungal therapies.

Tinea Nigra

Tinea nigra is a superficial mold infection of the stratum corneum that manifests as black, dark brown, or grey patches on the palms and soles; it is relatively uncommon in the US. Scale can be present, but it is typically minimal. Patients with hyperhidrosis or those living in humid climates are more commonly affected. Tinea nigra is occasionally confused with a melanocytic lesion because of its dark color. The two entities can be differentiated visually using dermoscopy, which shows brown strands or "pigmented spicules" in tinea nigra.[76,77] It is caused by a mold with a multitude of labels, including *Phaeoannellomyces* and *Hortaea* or *Exophiala werneckii*, which can be visualized using KOH preparation, revealing grey-brown to green hyphae and budding yeast cells. Topical antifungal agents such as miconazole, clotrimazole, and terbinafine are useful, as are drying solutions (e.g., aluminum chloride 20% solution).[78] Treatment of hyperhidrosis alone sometimes can lead to cure. Topical keratolytics (e.g., 3% topical salicylic acid) are also helpful in some cases.[78]

Piedra

White and black piedra are superficial fungal infections of the hair caused by *Trichosporon beigelii* and *Piedraia hortae,* respectively. They more commonly occur in tropical climates and manifest as soft concretions attached to scalp hair, but they also can occur in the axilla, pubis, and beard areas. These concretions can easily be confused with nits, hair casts, and other hair disorders; but on KOH examination, masses of septate hyphae (pigmented in black piedra) are seen within these concretions.[78] The differential diagnosis of piedra includes chronic intertrigo, hair casts, monilethrix, nits, pediculosis capitis, pediculosis pubis, tinea capitis, trichomycosis axillaris, trichoptilosis, and trichorrhexis nodosa.[79]

Treatment for both white and black piedra includes clipping or shaving hair in the affected area, along with topical antifungal therapy.[80] Ketoconazole 2% shampoo and topical keratolytics also can be effective.[78,79,81,82] Oral itraconazole (white piedra) or terbinafine (black piedra) may help to treat refractory or disseminated cases, which can occur in immunocompromised individuals. *T. beigelii* sepsis and organ dissemination can occur in low birth weight neonates and immunocompromised individuals.

Agents of Eumycotic Mycetoma

Pseudallescheria boydii (Anamorph *Scedosporium apiospermum*)

Elaine G. Cox, John Manaloor

A mycetoma (maduromycosis, Madura foot) is a noncontagious, localized chronic infection that affects skin, subcutaneous tissue, fascia, muscle, and bone. Characteristic clinical features of mycetomas include localized swelling, fistulous tracts, and suppurative drainage containing dense colonies (called *granules, sclerotia*) of the offending pathogen. Mycetomas can be divided into two general categories based on the causative agent: *eumycotic mycetoma* caused by one of the filamentous fungi, and *actinomycotic mycetoma* caused by *Actinomycetes.* Striking geographic differences occur in the proportion of mycetomas caused by each.[1] Agents of eumycotic mycetoma are considered in this chapter, and agents of actinomycotic mycetoma are considered in Chapter 195).

Microbiology

At least 32 species of filamentous fungi (Eumycetes) are recognized as causes of eumycotic mycetoma[2] (Box 255.1). All are common saprophytes of soil and vegetable matter. *Madurella mycetomatis,* the most common cause worldwide, accounts for 70% of eumycotic mycetoma infections, and *Pseudallescheria boydii* (anamorph *Scedosporium apiospermum*) and *Leptosphaeria senegalensis* each account for 10% of infections.[2] *P. boydii, Fusarium falciforme, M. mycetomatis, Madurella grisea,* and *Exophilia jeanselmei,* in decreasing order of frequency, are the most common causes of eumycotic mycetoma in the United States. Within these groups, additional species have been recognized that are distinct phylogenetically and clinically, and have distinct antifungal susceptibilities.[3] *Scedosporium aurantiacum, Pseudallescheria minutispora,* and *Madurella pseudomycetomatis* are among those recognized most recently.[4]

The agents of eumycotic mycetoma grow on Sabouraud dextrose agar, with optimal growth occurring between 25°C and 37°C.

Isolation is facilitated by agar containing chloramphenicol to inhibit growth of bacteria and cycloheximide to inhibit growth of extraneous molds, although cycloheximide also can inhibit growth of *P. boydii.* Incubation may be required for up to 6 weeks for growth. Identification of isolates is based on morphology and pigmentation of colonies, mechanisms of conidia production, and morphology of conidiophores and conidia. *Madurella* spp., *Neotestudina rosatii,* and *Pyrenochaeta* spp. do not sporulate readily, so special sporulation media and physiologic tests for carbohydrate and nitrate utilization may be needed for identification.

Virulence and Immunity

The agents of eumycotic mycetoma are relatively avirulent, opportunistic pathogens that do not invade intact skin. Infection results from direct fungal inoculation or contamination of wounds. Factors that predispose an exposed person to mycetoma have not been determined. Impaired cellular immunity may contribute, but has not been observed consistently. Fungal agents act as chemoattractants that stimulate the complement system to induce chemotaxis, leading to the accumulation of neutrophils around granules and in the centers of abscesses and sinus tracts. However, this immune response appears to be ineffective for inhibiting fungal replication.[5]

Antibodies to some antigens of the offending agent are produced after established infections and can be measured by counter-immunoelectrophoresis, immunodiffusion, and immunoblot methods.[6,7] Specific immunoglobulin G (IgG) and IgM antibody directed against the causative organism also can be measured by enzyme immunoassay (EIA).[6,7] In endemic regions, antibodies to fungi that cause mycetoma can be detected by EIA in both infected and uninfected people, confounding a serologic approach to diagnosis.[6,8] The effect of specific antibody on the course of infection has not been established. Antibody titers decrease in some patients after appropriate treatment. In some endemic regions, resolution of precipitation arcs identified with counter-immunoelectrophoresis techniques are used to guide therapy.[5]

Pathogenesis

Infection usually begins with a skin wound caused by a thorn contaminated with the causative fungus. Organisms proliferate, with development of localized skin and subcutaneous infection appearing as a papular lesion. Often unrecognized, the lesion enlarges slowly and painlessly over weeks to months. Inflammation can advance along fascial planes; hematogenous dissemination does not occur, although lymphatic spread has been described and is estimated to occur in about 2% of cases.[9]

The process slowly destroys contiguous soft tissues and has a predilection for infecting and permanently damaging bone (Fig. 255.1). Multiple sinus tracts are common, and exuded drainage contains granules consisting largely of densely packed fungal colonies. Some matrix substances found in granules in vivo are not found in cultures grown in vitro and may represent antigenic material derived from the fungus or the host. The size, shape, and color of fungal filaments and presence or absence of matrix material within granules vary with the offending agent.

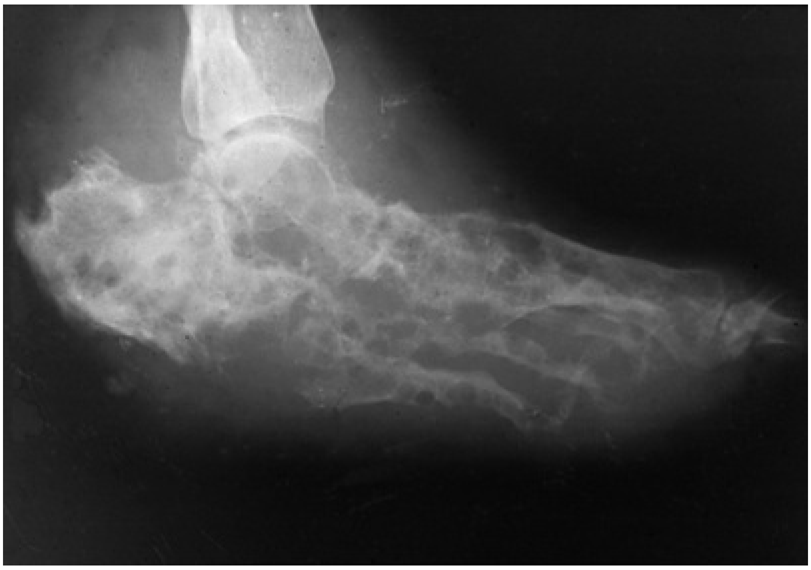

FIGURE 255.1 Radiograph of the foot of a 43-year-old farm worker with an 8-year history of foot swelling and fistulous drainage of suppurative material. *Madurella mycetomatis* was isolated from exuded granules. The radiograph shows extensive destruction of all bones of the foot with characteristic multiple lytic cavities and almost complete loss of normal bony architecture.

Except for the granules, histopathologic findings in mycetoma are nonspecific. Localized abscesses containing neutrophils and necrotic material surround granules. A subacute and chronic inflammatory response consisting of plasma cells, lymphocytes, multinucleated giant cells, and epithelioid cells surrounds the abscess (Fig. 255.2). An eosinophilic deposit (the Splendore-Hoeppli reaction) surrounds the granule and is thought to represent an immunologic response. Fibrosis ensues eventually and contributes to the gross anatomic deformities.[10]

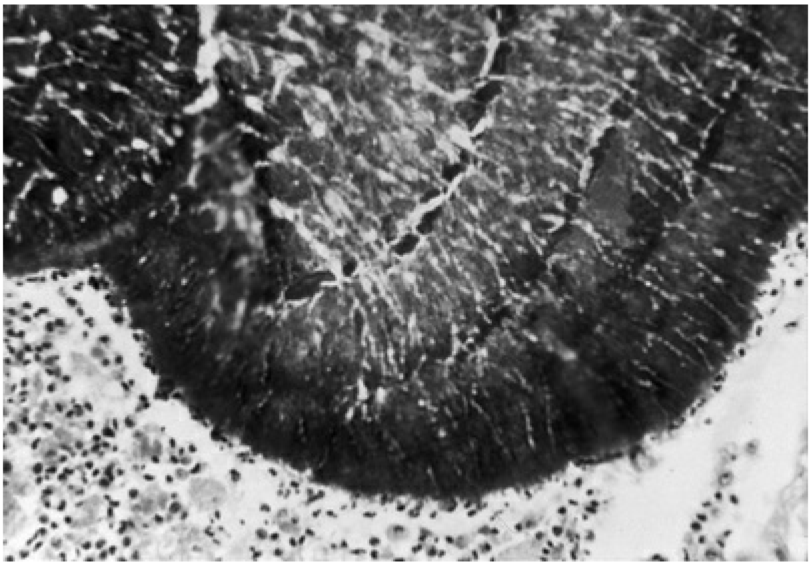

FIGURE 255.2 Hematoxylin and eosin−stained section of a brownish granule of *Madurella mycetomatis* containing radially oriented hyphae within a matrix of cement-like material. The granule is located within an abscess and is surrounded by acute inflammatory cells (original magnification, ×200).

Epidemiology

Most mycetomas occur in tropical or subtropical regions, mainly in areas where rainy seasons alternate with lengthy dry periods. Mexico,[11] India, Sudan,[12] Brazil, and Argentina have the highest incidence of reported infections. Eumycotic mycetomas are rare in the most temperate regions of the world, including the United States. Clinical diagnosis is becoming more common in individuals who travel to endemic regions.[6,13]

In endemic areas, the agents of eumycotic mycetoma commonly inhabit soil and plants. Thorn injuries, abrasions, and occupational activities that predispose to skin trauma and soil contamination lead to infection. A variety of pathogens have been reported among immunocompetent individuals.[14,15] Infection occurs most frequently in men 21 to 50 years of age, with a male-to-female ratio of 4 : 1,[13,16] and is infrequent among children. School-aged children younger than 11 years are most likely affected.[12] Poor nutrition or concomitant infections, often seen in resource-limited rural areas, are thought to increase the likelihood that exposure will lead to infection.

Clinical Manifestations

The initial lesion usually is a small subcutaneous nodule attached to the overlying skin. Fistulous tracts and sinus formation begin within several months to 1 year after infection. The purulent drainage contains granules. Subcutaneous nodules slowly enlarge, additional nodules appear, and new sinuses form as old sinus tracts heal. The progress of infection is slow, and medical attention frequently is not sought for many months or years. Extension contiguously and along fascial planes can lead to chronic bone infection. Systemic symptoms are absent unless secondary bacterial infection intervenes. Pain is not characteristic, and its presence often is associated with secondary bacterial infection of bone or progression of fistulous tracts.

Although infection can begin at any superficial anatomic site, mycetomas usually occur on extremities. About 70% affect feet, and 12% to 15% involve hands; other sites on extremities and the head and neck account for most of the remaining cases.[13] Chronic changes and destruction eventually affect most underlying structures[17] (Table 255.1). The result is a disfigured, scarred, swollen site with draining sinuses and functional impairment.

Tendon	Few alterations because of resistance
Nerve sheath	Hypertrophy
Lymphatics	Inflammatory reaction; embolization of granules possible
Lymphatic ganglia	Hypertrophy; dissemination rare
Bone	Periostitis, osteolysis, osteofibrosis
Peripheral nerve	Altered by sclerosis

Laboratory Findings and Diagnosis

In the presence of a lesion with tumefaction (indurated swelling), fistulous sinus tracts, and drainage that contains granules, the clinical diagnosis of mycetoma is straightforward. However, because treatment and prognosis differ for mycetomas caused by *Actinomyces* spp. or filamentous fungi, a specific diagnosis is necessary, and biopsy is required. Histopathologic findings in mycetoma are nonspecific and consist of acute and chronic inflammation, granulomatous changes, and fibrosis. On biopsy specimen, “grains” may or may not be observed because they are scattered along sinus tracts and vulnerable to sampling error. When present, they are large and surrounded by neutrophils. Careful examination of granules in tissue (see Fig. 255.2) or purulent material suggests the causative agent. Accurate confirmation requires fungal culture. Granules range in size from 0.2 to 5 µm and are often visible to the unaided eye. The color, texture, size, and shape of the granules provide important clues to the etiologic agent. Eumycotic mycetomas have granules that are black or white and soft or hard, with a cement-like matrix. Gomori methenamine silver nitrate staining of eumycotic granules shows wide, interwoven septate hyphae 2 to 5 µm in diameter; large swollen cells up to 15 µm in diameter also may be present at the periphery of granules. Actinomycotic infections have gram-positive, interlaced, thin filaments 0.5 to 1 µm in diameter, with coccoid and bacillary forms.[10]

To facilitate recovery of fungus, granules obtained from purulent material or tissue should be washed in normal saline that contains antimicrobial agents to inhibit growth of contaminating bacteria. Sabouraud dextrose agar is inoculated and incubated at 25°C and

37°C and examined for growth at 2-day intervals for 6 weeks. A secure etiologic diagnosis is established when a single agent is isolated from several granules.

Diagnostic modalities such as polymerase chain reaction[18] and matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry are becoming available to assist in identification of an isolated pathogen.[19–21]

Radiographic abnormalities can be seen in soft tissue and bone and include areas of increased soft tissue density (caused by granulomas) adjacent to normal soft tissue. Osseous lesions have a variable appearance (see Fig. 255.1); most are lytic cavities in bone that can contain large numbers of granules. Cortical bone also can be eroded by extrinsic irritation from contiguous soft tissue inflammation. Periosteal new bone formation can be seen as spicules oriented perpendicular to the long axes of long bones. Osteopenia results from disuse or impairment of perfusion. The "dot in circle" sign finding on magnetic resonance imaging is suggestive of mycetoma.[22,23] Ultrasonography can distinguish between the eumycotic mycetoma and actinomycetoma by appearance of their macrogranular characteristics.[24]

Although serologic tests have been investigated for use in diagnosis and to monitor therapy, standardized reagents are not available commercially.

Treatment and Special Considerations

Eumycotic mycetoma has a low cure rate overall, responding less favorably to treatment than do mycetomas caused by *Actinomyces* spp. Optimal management includes medical and surgical interventions. Initial surgical debulking generally is necessary, although medical therapy is a beneficial adjunct in an attempt to avoid amputation.[25,26] In general, response to antifungal agents is poor, perhaps because of changes within fungal cell walls that enable them to act as barriers to penetration of drug. These cell wall alterations also impair leukocyte adhesion to make the cell less penetrable to the respiratory burst products of inflammatory cells.

Most clinical experience with antifungal therapy has been with mycetomas caused by *M. mycetomatis.* Antifungal susceptibility testing might be helpful because there is considerable strain-to-strain variation in susceptibility. However, testing is not available widely, and standard cutoff values have not been well established.[5] Treatment with amphotericin B often is ineffective because of inherent resistance. Limited efficacy has been observed in a few patients treated with liposomal amphotericin formulations.[27] Fluconazole is ineffective largely, but newer azoles have demonstrated clinical efficacy in the treatment of eumycotic mycetoma.[9,28,29] Ketoconazole (200 mg per dose given twice daily in adults) historically was the most frequently used agent and was successful in about 70% of cases.[30] However, ketoconazole was not successful in treating eumycetomas caused by *M. grisea, P. boydii (S. apiospermum),* and *Acremonium* spp.[31] Griseofulvin (500 mg per dose given three times daily in adults) used for patients who did not respond to ketoconazole was infrequently successful. Itraconazole initially showed a favorable response in only 40% of patients; more recent experience demonstrates good tolerability and efficacy.[30,32–34] Voriconazole has been used successfully for treatment of subcutaneous infections with *S. apiospermum* when administered intravenously followed by orally, as an adjunct to debridement.[26,35] In clinical studies, posaconazole was more effective than voriconazole in treating *P. boydii* in certain clinical scenarios.[9,16,20,29,36–39] The echinocandin class appears to have little to no therapeutic potential in early clinical studies, although there is some evidence of activity of caspofungin against *P. boydii* in vitro.[40] Agents under investigation, such as ravuconazole and isavuconazole, show promise for superior efficacy.[28,29,41] Additional strategies, such as combination therapy, show little promise except for possible synergy between ciprofloxacin and posaconazole.[42,43]

Although there are no controlled studies of duration of treatment, antifungal therapy should be continued for at least 10 months or at least 3 months after resolution of inflammation. Decreasing antibody titer may be a marker of effective therapy[5]; however, standardized serologic tests are not available.

Incision and drainage of abscesses, debulking of large masses, and excision of sinus tracts facilitate healing, reduce pain, and may mitigate need for amputation. Length of antifungal therapy often can be reduced with adequate debulking procedures. Excision can be curative if performed when lesions are small and have not involved bone; a wide margin of uninfected tissue should be removed in such cases.[19,30] Without antifungal therapy, relapse after resection occurs in more than half of cases. Other treatment modalities, such as topical negative pressure, have minimal success.[25]

Prevention

In endemic areas, prevention requires protection from injuries prone to contamination by soil or vegetable matter. Improvements in hygienic standards, reduction of occupational injuries, and use of adequate footwear and protective clothing should reduce the frequency of mycetoma. Education of people at risk to seek medical intervention early, when cure is more likely and loss of limb can be avoided, is essential. New strategies of education have included point-of-care attempts at integrated management.[12]

Pseudallescheria boydii (Scedosporium apiospermum)

P. boydii (S. apiospermum) is a saprophytic fungus with worldwide distribution in soil, water, and feces of domesticated animals. *P. boydii* is an opportunistic pathogen that rarely causes infection in healthy, immunocompetent hosts. *P. boydii* causes about 10% of eumycotic mycetoma and also is responsible for a variety of other infections, especially in immunocompromised people.[2,44] Nonmycetomatous infections caused by *P. boydii* are termed *pseudallescheriasis.*

Microbiology

P. boydii is a member of the class Ascomycetae and, in contrast to most pathogenic fungi, exists in tissue in its teleomorphic (sexual) form. The anamorph (asexual form) is termed *S. apiospermum* and can cause infection that is clinically indistinguishable from infection caused by the teleomorph. The mold grows on Sabouraud and most standard media, and matures in 7 days. Growth can be inhibited by cycloheximide contained in some selective agars used for primary isolation. On oatmeal agar, white colonies grow rapidly at 25°C and later turn to grey. Hyphae are yellow-brown and 2 to 3 μm in diameter. Asci are 12 to 18 μm × 9 to 13 μm in diameter and contain 8 ascospores. Two morphologic types of asexual conidia are produced, the most common being *Scedosporium* type and a smaller *Graphium* type. In tissue sections, the hyphae of *P. boydii* are branched, septate, hyaline, and hematoxylin stain positive. Morphologic distinction of *P. boydii* hyphae from hyphae of *Aspergillus* and other hyaline molds is not possible, and direct immunofluorescent testing is needed. *P. boydii* likely does not represent a single entity but rather is a complex with at least 6 known species.

Epidemiology

P. boydii is a common inhabitant of water, soil, and manure and usually gains entry to a host through accidental trauma or aspiration. Although worldwide in distribution, considerable regional differences occur in the frequency of isolation of *P. boydii* from people with clinical illnesses.[45] This discrepancy may be attributable to differences in strain virulence.[37,46]

Clinical Manifestations

Almost 99% of infections caused by *P. boydii* are mycetomas. The presence of granules (sclerotia) is a distinguishing feature of true mycetomas. Infections caused by traumatic implantation of *P. boydii,* but which do not contain granules, are termed *pseudallescheriasis.*[47]

P. boydii is found occasionally as a commensal in preexisting lung cavities and in paranasal sinuses. Respiratory tract illnesses attributed to *P. boydii* follow inhalation of contaminated material and include pneumonitis as well as fungus balls in lung cavities and paranasal sinuses.[15,48] Infections that occur in immunocompetent children usually are localized and result from contaminated puncture injuries. Eyes and periorbital structures, skin and subcutaneous tissue, and osteoarticular structures are affected most commonly.[49]

Infections in an immunocompromised host can be localized but are increasingly reported to result in invasive and disseminated disease. Life-threatening manifestations occur most often in patients with solid-organ transplants,[50] hematologic stem cell transplants,[51] hematologic malignancies,[52] HIV infection, or chronic granulomatous disease and in people receiving immunosuppressive therapy.[20,53] In these groups of patients, systemic infection, meningitis, brain abscess, keratitis and endophthalmitis, otomycosis, endocarditis, indwelling device-related infection, central nervous system infections, and other invasive infections are common.[54] Mortality rates as high as 75% are reported in patients with central nervous system and progressive disseminated infections.[44,55–57] Clinical findings in these settings often mimic findings caused by *Aspergillus* or *Fusarium* infections.

Diagnosis

Diagnosis is confirmed by isolating the offending agent from a normally sterile site. Culture has been the gold standard, but identification by polymerase chain reaction is increasingly important and used more widely.[18,58] Because antifungal susceptibility patterns differ for these organisms, laboratory confirmation is needed.[59] Rare instances of coinfection have been identified.

Treatment

P. boydii often is resistant to amphotericin B,[60] and its use in these infections has been associated with poor clinical response as well as recurrence after seemingly effective therapy.

Development of the first triazoles provided new, but limited, therapeutic options. Fluconazole has no activity against *P. boydii*.[53] Itraconazole[61–63] and ketoconazole[64] have been used clinically with mixed results. Both voriconazole and posaconazole have activity in vitro.[39,41,60,65–70] Voriconazole has been used successfully in cutaneous infections,[26,35] disseminated disease,[55,57] and pulmonary infections.[15] Voriconazole appears to have good penetration into the cerebrospinal fluid and has been used in treating central nervous system disease.[55,57,69,71–75] Because of the wide spectrum of disease manifestations that appear to respond favorably, voriconazole is considered by most experts to be the drug of choice.[9] Posaconazole also has good activity in vitro against *S. apiospermum*[56] but also has adequate penetration into the central nervous system. Posaconazole has been used successfully to treat brain abscesses in immunocompromised hosts who were refractory to treatment with other agents.[1,16,69,76,77] An isolated report suggests a potential role for potassium iodide.[78] Drainage or excision of infected tissue, when possible, is an important adjunct to therapy.[1,57] Mortality in invasive infections is high if operative management is not feasible.

The optimal duration of antifungal therapy has not been established and must be individualized. In immunocompetent hosts in whom lesions can be excised, antifungal treatment may be discontinued after 6 months.[1] Patients with underlying conditions that make clearance of the fungus unlikely may require treatment indefinitely. Consultation with experts is recommended in managing such patients.

Key Points

Eumycotic Mycetoma (Maduramycosis, Madura Foot)

Definition

- Noncontagious, chronic infection of skin, subcutaneous tissue, fascia, muscle, and bone caused by a variety of filamentous fungi

Microbiology

- *Madurella mycetomatis* (70%); *Pseudallescheria boydii* (anamorph *Scedosporium apiospermum*) (10%); *Leptosphaeria senegalensis* (10%)

- At least 32 species of filamentous fungi (see Box 255.1)

Epidemiology

- Tropical, subtropical areas with rainy seasons and dry seasons. Mexico, India, large regions of Africa, Central and South

America. Rare in temperate regions; infrequent among children

- Skin injury predisposes to inoculation of contaminated wounds

Clinical Features

- Lesions often affect feet (70%) and sometimes hands (15%).
- Subcutaneous nodule(s) early; fistulous tracts in weeks to months
- Purulent drainage contains granules.
- Lesions usually are painless, and systemic symptoms are absent unless secondarily infected with bacteria.
- Slow progression along fascial planes often leads to bone infection.

Diagnosis

- Tumefaction, fistulous sinus tracts, and drainage containing granules often are present.
- Clinical, radiographic, and histopathologic findings are similar in actinomycotic mycetoma.
- Examination and culture help to distinguish between entities and informs appropriate antimicrobial therapy.
- Polymerase chain reaction and matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) can assist in final characterization of agents causing mycetoma.

Treatment

- Eumycotic mycetomas respond less favorably than infection caused by *Actinomyces.*
- Surgical debulking and drainage of abscesses is needed in association with antifungal therapy.

Classification of Parasites

Peter J. Hotez

Although all infectious agents of humans are parasites, by convention, parasitic diseases often are defined as diseases caused by protozoa or helminths. Parasitic protozoa and helminths sometimes are referred to as animal parasites to distinguish them from bacteria, fungi, and viruses. This distinction has a historical basis. Parasitology (the study of animal parasites) emerged as a separate discipline from microbiology as a result of nineteenth-century scientific investigations conducted outside the mainstream of science in Europe. Animal parasites were considered "exotic" because many initially were described by European investigators working in the tropics. The life cycle of filariasis was elucidated by Manson (British) in China, malaria by Ross (British) in India, ancylostomiasis by Looss (German) in Egypt, and schistosomiasis by Bilharz (German) in Egypt.

The animal parasites of humans and their vectors constitute a diverse array of eukaryotic organisms that span many phyla (Box 256.1).[1] The major endoparasitic helminths of humans belong to the phyla Platyhelminthes (flatworms) and Nematoda (roundworms). The endoparasitic protozoa are a diverse group of several thousand eukaryotic unicellular animals.[2] Together, the parasites exert an enormous toll on human life and health. The Global Burden of Disease Study estimated that 854,600 people died from malaria in 2013, with most of those deaths from *Plasmodium falciparum* among children.[3] In that same year, an estimated 62,500 people died from visceral leishmaniasis, 10,600 died from American trypanosomiasis (Chagas disease), and 6900 deaths were due to African trypanosomiasis. Intestinal parasites were also major childhood killers, with cryptosporidiosis causing an estimated 41,900 deaths and amoebiasis 11,300 deaths among children younger than 5 years.

In contrast, the helminth infections caused many fewer deaths but a high degree of disability. The Global Burden of Disease Study estimated that more than 1 billion people were infected with helminth infections in 2010, including ascariasis (819 million people), trichuriasis (465 million), hookworm disease (439 million), and schistosomiasis (252 million).[4] These helminth infections were responsible for an estimated loss of 8.5 million disability-adjusted life years.

Despite their public health importance, most of the human parasitic diseases have been neglected by the scientific, medical, and public health communities.[5,6] Their neglect stems from the observations that parasitic diseases generally occur among the poor and more often than not occur in remote and rural areas where they are hidden from view. In addition, because they result in chronic disability, they are themselves poverty promoting. In some cases, parasitic diseases have stigmas attached. Hence the major chronic parasitic infections of humans often are referred to as *neglected tropical diseases*.[5–7] Since 2006, global efforts have been implemented to provide low-cost or drug company–donated treatments for 7 of the most common neglected tropical diseases (i.e., ascariasis, trichuriasis, hookworm, schistosomiasis, lymphatic filariasis, onchocerciasis, and trachoma) in programs of mass drug administration.[5–7] The United States Agency for International Development (USAID) recently estimated that more than 1 billion people have received access to essential neglected tropical disease medicines through its programs of mass drug administration. However, the commercial markets for new drugs, vaccines, and diagnostics are extremely small, and there have been few incentives for pharmaceutical companies to undertake drug discovery and development programs for parasitic and neglected tropical diseases. As a result, many of the drugs still in use today for parasitic infections were first discovered in the middle of the twentieth century.[6] There is some optimism that the recent creation of new nonprofit product development will accelerate development and clinical testing of new drugs and vaccines for neglected tropical disease.[6]

Parasitic Archeozoa and Protozoa

Some investigators are of the opinion that the old classification, in which a single phylum of protozoa encompassed all unicellular eukaryotic microorganisms, is not validated by the wealth of new ultrastructural and molecular taxonomic data. Armed with newly developed molecular probes, tools, and approaches to cladistic analysis, biologists are re-examining the classification of these organisms. For instance, the parasite *Giardia lamblia* has been shown to lack mitochondria and to contain ribosomal RNA sequences that more closely resemble those of bacteria.[8,9] It has been proposed that this organism represents an evolutionary transition between prokaryotic and eukaryotic microorganisms.[10] Similarly, the obligate intracellular microsporidia have ultrastructural features, such as ribosomes and a unique complex extrusion apparatus, that are distinctly different from those found ordinarily in protozoa. Some experts think that these parasites are different enough to justify exclusion from Protozoa. Corliss reclassifies them as Archeozoa, a term that reflects their evolutionary transitional nature.[1] Typically, members of Archeozoa primitively lack certain organelles, such as mitochondria, peroxisomes, and typical Golgi bodies. In contrast, one or more of these organelles is present characteristically in Protozoa. In response to these observations, some microbiologists have elevated both the Archeozoa and Protozoa to the status of a taxonomic kingdom to more accurately describe the diversity of these two groups (Box 256.2). In this classification, the former subphyla of protozoa, specifically, Apicomplexa, Ciliophora, and Rhizopoda, are raised to independent phyla within the kingdom of Protozoa. Clinicians prefer to identify unicellular eukaryotic microorganisms on the basis of their mode of transmission (e.g., enteric, arthropod-borne) or site of parasitism within humans (e.g., blood, gastrointestinal tract) (Table 256.1). However, a sound taxonomic understanding of these microorganisms fosters an understanding of their pathophysiology and predicts the activity of antiparasitic agents. For instance, albendazole might be useful for treatment of Microspora but not for more conventional protozoa.

Almost certainly our knowledge about classification and biology of the Archeozoa and Protozoa will increase substantially in the coming decade. The new knowledge will be derived from the dozen or more protozoan genome projects completed within the decade.

The projects include completion of genomes for some of the most important protozoan pathogens.[11] In every case, these genome projects are revealing promising drug targets and new insights into evolution of parasitic protists.

Parasitic Animalia

The endoparasitic worms of humans belong to the phyla Nematoda and Platyhelminthes. Nematodes are nonsegmented cylindroid roundworms that predominantly are free-living forms inhabiting the soil and water. Many species of nematodes also are plant parasites of enormous agricultural and economic importance. Almost every vertebrate can harbor one or more species of endoparasitic nematodes. Humans are no exception, and nearly one fourth of the world's population is infected with at least one species of nematode (e.g., *Ascaris lumbricoides, Trichuris trichiura,* and the hookworm *Necator americanus*).[3,12]

Human parasitic nematodes vary enormously in length from just over 200 µm (microfilariae) to more than 120 cm *(Dracunculus)*. Their size, however, does not correlate with pathogenicity. One of the smallest nematodes, *Strongyloides stercoralis,* is among the most virulent of human pathogens. Nematodes are surrounded by a resistant cuticle and move by means of a complex muscular system; their digestive system is divided into an oral (buccal) cavity, esophagus, midgut, hindgut, and anus. Frequently, these structures are modified in the parasitic forms. For instance, the oral cavity of hookworms is enlarged and armed with teeth or cutting plates to ingest intestinal mucosa, and the esophagus is equipped with large exocrine glands that may contain hydrolytic enzymes for exodigestion.[12] The reproductive organs are highly developed in parasitic nematodes, particularly in females, and reflect their capacity to give rise to progeny. An adult female ascarid can release 200,000 eggs per day. Most nematodes have one or more life cycle stages, such as an egg or larva, that develop outside the host. It is convenient to categorize nematodes on the basis of their site of external development and the mechanism of entry into their definitive human host. Therefore we frequently group endoparasitic nematodes according to whether they are transmitted through contact with soil *(Ascaris)*; have an invertebrate intermediate host such as an insect *(Wuchereria)*, crustacean *(Dracunculus)*, or mollusk *(Angiostrongylus)*; or have another vertebrate host with acquisition by the ingestion of undercooked meat *(Trichinella)* (Table 256.2). Several new genome projects for human nematode parasites are underway (http://www.nematodes.net and http://www.nematodes.org), which should add considerably to our fundamental knowledge.

Two endoparasitic classes of the phylum *Platyhelminthes* are important medically: trematodes and cestodes (Table 256.3). Human trematodes include blood flukes (schistosomes), intestinal flukes, and tissue flukes. Each species of human trematode also has external life cycle stages in one or more intermediate hosts. At least one intermediate host is always a mollusk. The adult fluke is either monoecious, having both sexes (hermaphroditic), or diecious, having separate sexes. Monoecious flukes reproduce by self- or cross-fertilization, whereas diecious trematodes live in copula as separate sexes. Except for the schistosomes, all human trematodes are monoecious. Eggs released by adult flukes typically hatch in water and give rise to free-living ciliated miracidia that seek their molluscan intermediate host. Miracidia are pluripotent and, when inside the snail, ultimately generate large numbers of cercariae.

Cercariae exit the snail and enter their definitive human host by direct skin penetration (schistosomes) or encyst as metacercariae in a second intermediate host such as fish (*Clonorchis*) or vegetation *(Fasciola)* before ingestion. In terms of prevalence and chronic disease burden, the two most important trematodes are *Schistosoma haematobium* and *S. mansoni.* More than 200 million people are infected with either of these two parasites, most in Africa, although some estimates suggest that this number could be two or more times higher.[3,13,14] Two schistosome genome projects have been completed.[15]

In their definitive vertebrate host, cestodes are parasitic tapeworms with a gastrointestinal tract attachment apparatus (scolex) and a series of proglottid segments (strobila). Each proglottid segment contains both male and female reproductive organs and typically fills with eggs before detachment in feces. Ingestion of eggs by an intermediate host results in the liberation of larvae that frequently migrate to muscle as a final destination. Humans acquire tapeworms when they ingest the larval stage contained within arthropods or uncooked meat. Much more severe disease results when humans serve as the “accidental” intermediate host for cestodes by ingesting tapeworm eggs. Such intake can result in cysticercosis after ingestion of the eggs of *Taenia solium* or in hydatid disease after ingestion of the eggs of *Echinococcus granulosus.* Cysticercosis is emerging as an important cause of epilepsy in children, including children living in North America.

Ectoparasites (Lice and Scabies)

Dirk M. Elston

Pediculosis

The Parasites, Virulence, and Pathogenesis

Pediculosis is an infestation by one of several species of sucking lice of the phylum Arthropoda, class Insecta, order Phthiraptera, suborder Anoplura, family Pediculidae or family Pthiridae. The three types of lice that infest humans are *Pediculus humanus capitis* (the head louse), *Pediculus humanus humanus* (the body louse), and *Phthirus pubis* (the crab louse).

Louse infestation spreads readily, and the host response offers little protection against reinfestation. Resistance to chemical pediculicides is widespread, especially knockdown resistance to permethrin related to a double gene mutation (*T929I* and *L932F*). Glutathione-*S*-transferase–based resistance also has been implicated in pyrethroid resistance. Mono-oxygenase–based resistance is common but can be overcome by synergistic agents such as piperonyl butoxide.

Transfer of lice is optimal when hairs are parallel and slow moving, as when two individuals are sleeping or napping. Except in very humid climates, head lice lay nits very close to the scalp (within 1 to 2 mm), and adult head lice can survive for about 24 hours off of the scalp.

Epidemiology

Head louse infestation affects about 6 to 12 million people per year in the United States alone, with highest prevalence among children between the ages of 3 and 12 years. Transmission occurs by means of direct contact or through fomites such as hats and scarves. Crab lice usually are spread sexually. Adolescents with pubic lice are roughly twice as likely as uninfested adolescents to have chlamydial or gonococcal infection. Among the homeless, body lice serve as vectors for *Bartonella quintana* endocarditis, epidemic typhus, louse-borne relapsing fever, and trench fever.

Clinical Manifestations and Diagnosis

Head louse infestation manifests with pruritus of the scalp and posterior cervical lymphadenopathy. Body louse infestation produces a widespread dermatitis that can mimic a viral exanthem. The finding of characteristic bluish hued to copper-colored skin discoloration, *maculae cerulea*) should prompt a search for body lice or nits in the seams of clothing. Crab louse infestation involves pubic hairs as well as hair on the chest, abdomen, and legs. Patients can present with generalized pruritus. Maculae cerulea (Fig. 257.1) identical to those seen in body louse infestation can be present in crab louse infestation, and underwear commonly is stained with bloody louse excrement.

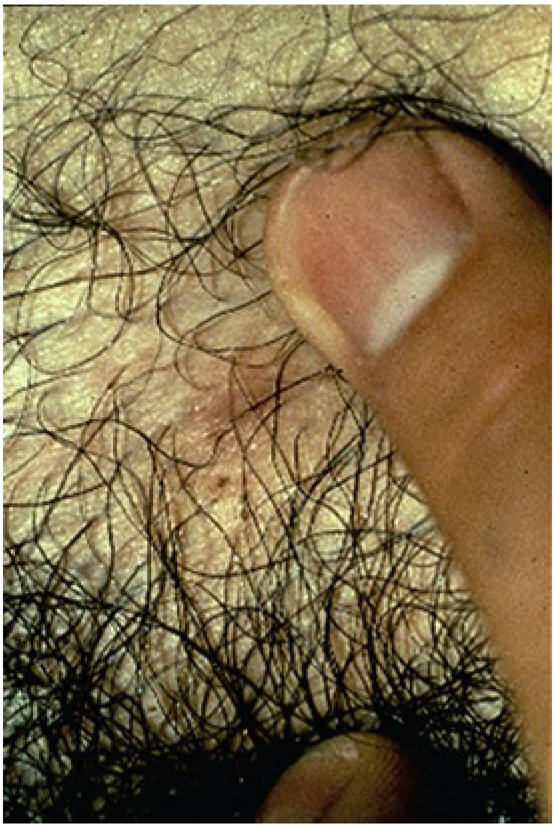

FIGURE 257.1 Maculae cerulae caused by bite of the body louse.

The diagnosis is made by finding lice or nits in the hair or seams of clothing (Figs. 257.2 to 257.5).

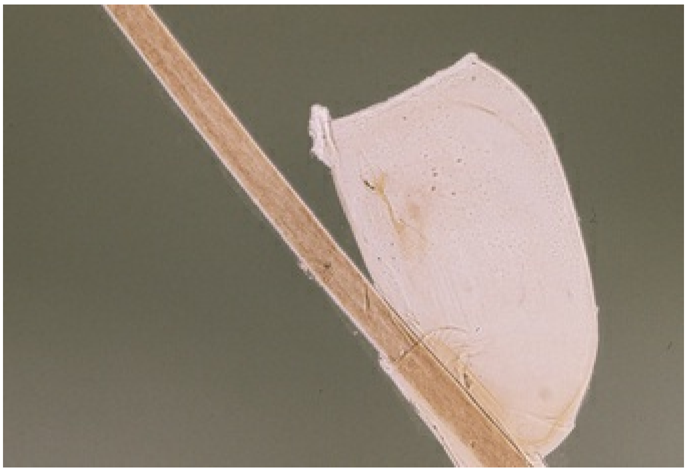

FIGURE 257.3 Empty egg case on shaft of hair.

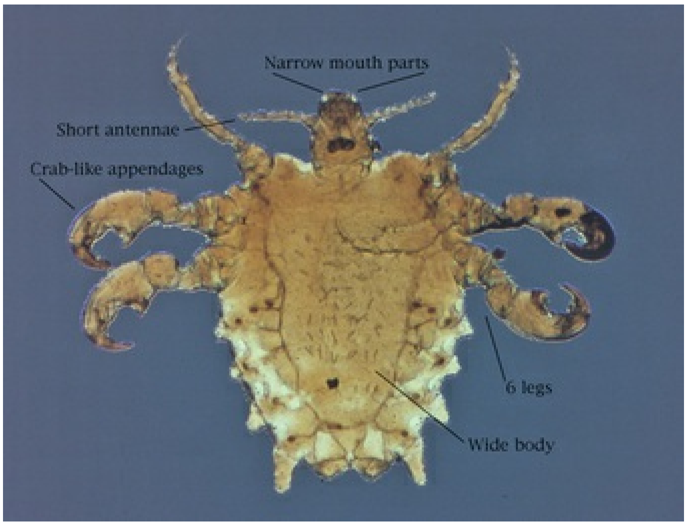

FIGURE 257.4 *Phthirus pubis* (crab louse).

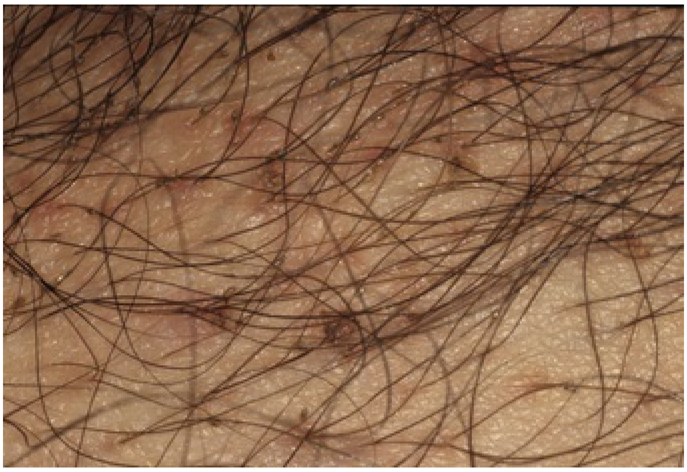

FIGURE 257.5 Crab lice in pubic hair.

Treatment

Shaving of all parasitized hair will eradicate head and pubic lice but is not cosmetically acceptable in most societies. Mechanical removal by wet-combing is labor intensive, and compliance is poor. Dilute solutions of vinegar or formic acid are not capable of dissolving nit cement but can facilitate combing by flattening the hair cuticle.

Topical products (Table 257.1) are recommended treatment for louse infestations. Considerations for choosing therapy include over-the-counter availability, toxicity, cost, and resistance patterns of lice.[1] Repeat application of topical agents at 7 days is generally recommended for all agents except lindane, but recent evidence suggests that ova can take as long as 13 days to hatch, suggesting that 3 applications a week apart may be optimal timing.[2] Lindane is no longer recommended for treatment of lice.

[a] Levels of evidence: IA, meta-analysis of randomized controlled trials; IB, at least one randomized controlled trial; IIA, at least one controlled study without randomization; IIB, at least one other type of quasi-experimental study.

[b] Most labels suggest repeat application in 1 week, but an extra application at 2 weeks may be needed in many patients

[c] The cream should be applied to the entire body, including the head in infants. Care should be taken to apply a thick coat under the nails, in the umbilicus, axillae, web spaces, wrists, ankles, and genitalia. Close contacts should be treated concurrently.

Topical Agents

Benzyl Alcohol 5% (Ulesfia Lotion).

Benzyl alcohol lotion is approved by the US Food and Drug Administration (FDA) for children 6 months and older and may be the treatment of choice. The quantity applied must be sufficient to saturate the hair completely for 10 minutes. FDA phase 3 drug trials comparing the product to vehicle placebo for two 10-minute applications showed it to be safe and effective ($P < 0.001$).[3] Toxicity has been reported with intravenous exposure to benzyl alcohol in neonates and low birth weight infants. The “gasping syndrome” (characterized by central nervous system depression, metabolic acidosis, and gasping respirations) has been associated with benzyl alcohol dosages of >99 mg/kg/day. The product label indicates that benzyl alcohol was quantified in a single plasma sample in 4 out of 19 subjects (21%) after topical application, including 3 subjects in the 6 months to 3 years age group at 0.5 hour after treatment. The level ranged from 1.97 to 2.99 µg/mL—levels unlikely to produce toxicity. With topical use, benzyl alcohol can induce histamine release and produce scalp itching and eye irritation.

Permethrin 1% Lotion (Nix).

Permethrin is a synthetic pyrethroid neurotoxin available over the counter as a 1% cream rinse and is approved for use in children 2 months and older. Permethrin acts on sodium-gated channels resulting in paralysis (knockdown) and subsequent death of the louse. Knockdown resistance is now widespread and identified readily by gene mutation or lack of initial immobilization.

Resistance to permethrin commonly crosses over to pyrethrins as well as to the other pyrethroids.[4]

Pyrethrin/Piperonyl Butoxide (Rid, A200).

Pyrethrins are botanically derived, over-the-counter pediculicides that act as neurotoxins. Piperonyl butoxide typically is added to potentiate the insecticidal effect. Allergic contact dermatitis can occur in people who are sensitive to Compositae plants and ragweed. It should only be used in children older than 2 years.

Spinosad 0.9% Suspension (Natroba).

Spinosad topical suspension is a novel neurotoxin indicated for the treatment of head lice in children 6 months and older. It contains a mixture of spinosyn A and spinosyn D in a ratio of approximately 5 : 1. The active ingredient is derived from the fermentation of a soil actinomycete bacterium, *Saccharopolyspora spinosa.* The suspension is applied for 10 minutes. The suspension contains benzyl alcohol that may contribute to the product's efficacy.[5] The product label indicates that benzyl alcohol was quantifiable (>1 µg/mL) after application in 6 out of 26 subjects (25%), including 4 out of 12 subjects in the 6 months to <2 years age group. The highest observed concentration was 2.37 µg/mL, a range similar to that observed after topical Ulesfia application.

Ivermectin 0.5% Lotion (Sklice Lotion).

Topical ivermectin lotion is indicated for the topical treatment of lice in children 6 months and older, with a single 10-minute application, and compares favorably with oral ivermectin.[6] Adverse effects include skin and eye irritation. Ivermectin is derived from the fermentation of a soil-dwelling actinomycete, *Streptomyces avermitilis*. Absorption of ivermectin was evaluated in 20 lice-infested subjects (13 weighing 15 kg or less). The mean plasma maximal concentration (0.24 ± 0.23 ng/mL) is much lower than that observed after oral administration.

Malathion 0.5% (Ovide).

Malathion is a weak organophosphate cholinesterase inhibitor that acts as a neurotoxin. Currently, malathion resistance is rare in the

United States but is more common in the United Kingdom. Although malathion is labeled for use in children 6 years and older, recent studies showed no cholinesterase inhibition in children 2 to 6 years of age. Flammability of malathion preparations compounded in isopropyl alcohol has resulted in human injury about once in >1 million prescriptions filled. Efficacy for eradication of louse infestation in the US is 97% to 98%.[7]

Carbaryl.

Carbaryl is a carbamate insecticide once used commonly in the UK, where over-the-counter sales have been restricted because of concerns about carcinogenicity. Acetylcholinesterase-based resistance is emerging.

Alternative Agents

Oral Ivermectin.

Ivermectin may have some potential for neurotoxicity, and safety and efficacy in the setting of pediculosis remain to be established. Safety has not been proved in children <15 kg (33 lb). A study comparing oral ivermectin (at a dose of 400 μg/kg of body weight) with 0.5% malathion lotion, each given on days 1 and 8, found ivermectin to be more effective. It should be noted that the dose of ivermectin used was twice that typically prescribed for this indication.[8,9]

Others.

Dimeticones kill head lice by physical means and appear promising as an alternative to neurotoxins. Isopropyl myristate, 1,2-octanediol, and various plant-based products also demonstrate some efficacy. A combination product containing 50% isopropyl myristate and 50% cyclomethicone was approved in Canada in 2006 and marketed under the name Resultz. At least 3 botanical shampoos have shown greater efficacy compared with carbaryl—*Zanthoxylum limonella* Alston, *Acorus calamus* Linn., and *Phyllanthus emblica* Linn.—and several compare favorably with malathion.[10,11] Crotamiton (Eurax) is better known as a second-line antiscabetic agent but also has some activity as a pediculicide. Trimethoprim-sulfamethoxazole once was thought to act on lice by killing bacterial flora necessary for the synthesis of B vitamins in the louse's gut, but recent evidence suggests limited efficacy. Lice in clothing can be killed by ironing or machine laundering at 50°C and machine drying on a hot cycle.

Special Considerations

Variations in cerebral p-glycoprotein, cytochrome P450 monooxygenases, esterases, and alcohol and aldehyde dehydrogenases make some individuals more susceptible to toxic effects of pesticides.[12] Reports suggesting a possible association between pesticides and childhood leukemia have raised concern about the use of pediculicides in children, particularly pyrethroids.[13] Congenital leukemia with a *11q23/MLL* rearrangement has been reported in a child whose mother had heavily abused aerosolized permethrin during pregnancy, and laboratory evidence that incubation of a BV173 cell line with permethrin can induce MLL cleavage suggests a possible causal association.[14]

Prevention

“No-nit” policies have not been shown to reduce the incidence of louse infestation but exclude many children from school. A better approach is through community education and louse inspections during outbreaks. Piperonal is a pediculicide that also exhibits repellent effects.

Key Points

Diagnosis and Management of Louse Infestation

Microbiology

- Bloodsucking lice of the phylum Arthropoda, family Pediculidae or family Pthiridae.

Epidemiology

- Transmission occurs by direct contact or through fomites such as hats and scarves.

- Crab lice usually are spread sexually.

Treatment

- Benzyl alcohol lotion 5% (Ulesfia) is the first US Food and Drug Administration (FDA)-approved nonneurotoxic louse treatment available in the United States.

- Other topical treatments include a number of neurotoxic agents such as spinosad, topical ivermectin, pyrethrins with piperonyl butoxide, permethrin, malathion, and carbaryl.

- Alternative agents include oral ivermectin, dimeticones, botanicals, crotamiton, and isopropyl myristate/cyclomethicone.

Duration of Therapy

- Most topical products are labeled to be applied twice, but off-label treatment with 3 applications 7 days apart may target late-hatching ova more effectively.

Scabies

The Parasites, Virulence, and Pathogenesis

Human scabies usually is caused by the mite *Sarcoptes scabiei* var. *hominis,* an obligate human parasite and member of the class Arachnida, subclass Acari, order Astigmata, and family Sarcoptidae.[15] Animal mange mites occasionally can produce symptoms in humans.

Sarcoptes scabiei elicits a mixed type I/type IV hypersensitivity reaction. Cross-reactivity occurs between the scabies mite and the house dust mite. During infestation, there is marked increase in the secretion of interleukin-6 (IL-6) and vascular endothelial growth factor. IL-6 activates Th1 CD4$^+$ lymphocytes to secrete IL-2, promoting lymphocyte proliferation and differentiation.

Direct skin-to-skin contact for 15 to 20 minutes is required for transfer of mites. The average person harbors only 5 to 12 mites, but those with crusted scabies can shed mites by the thousands.

Epidemiology

Roughly 300 million cases of scabies occur in the world each year. Risk factors include overcrowding, immigration, poor hygiene, poor nutritional status, homelessness, dementia, and sexual contact. In developing countries, scabies infestation and associated impetigo appear to be important risk factors for chronic kidney disease.

Clinical Manifestations and Diagnosis

The diagnosis should be suspected in anyone with intense, intractable, generalized pruritus. Often, multiple family members are affected, and the itch typically is worse at night. The eruption has a predilection for anterior axillary folds, periumbilical skin, the nipple area in females, volar surface of the wrists, interdigital web spaces, the belt line, penis, scrotum, and ankles (Figs. 257.6 to 257.8). Mite burrows are serpiginous 1- to 4-mm keratotic lines, often punctuated by a small vesicle at one end, which houses the mite. In infants and young children, scalp, face, and neck can be heavily involved. Pustules on the palms and soles are typical in infantile scabies. After puberty, genital nodules are common. In endemic areas, widespread impetigo generally is presumed to indicate scabies infestation. Crusted scabies in children with Down syndrome appears with whitish flaky crusts with striking involvement of the hands and ears. In infants and young children, a dense Langerhans cell infiltrate can result in misdiagnosis as Langerhans cell histiocytosis.

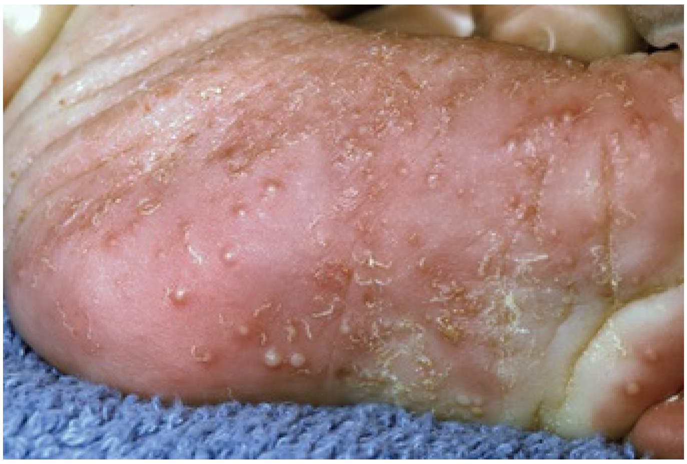

FIGURE 257.7 Acral pustules of scabies.

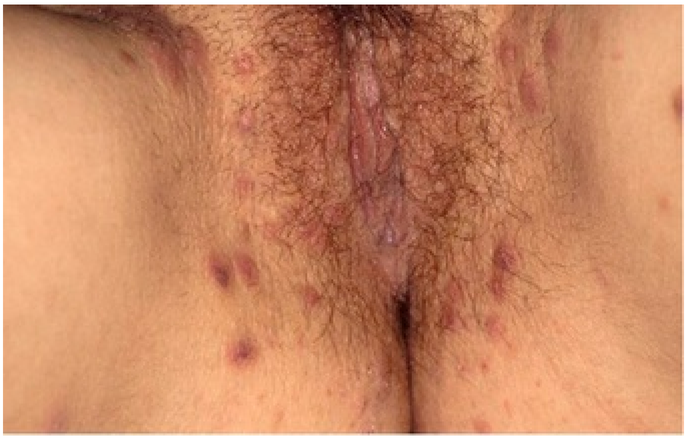

FIGURE 257.8 Scabies nodules.

The diagnosis is confirmed by identification of the mites, eggs, or fecal pellets in scrapings from burrows (Fig. 257.9). Fluorescent microscopy can be used to highlight fecal debris and fragments of ova. *S. scabiei* DNA polymerase chain reaction assays exist but are rarely used in clinical practice.

Treatment (Table 257.1)

First-Line Treatments

Permethrin 5%.

Permethrin cream 5% should be applied to the entire body, including the head in infants, left on for at least 8 hours and repeated in 7 to 10 days. A Cochrane group review of interventions for scabies concluded the following: topical permethrin remains the most effective treatment for scabies, ivermectin appears to be an effective oral alternative; more research is needed on the effectiveness of malathion.

Precipitated Sulfur 6% to 10% in Petrolatum.

Sulfur is the oldest recorded treatment modality for scabies and remains in common use worldwide. Despite a lack of controlled clinical trials, sulfur generally is acknowledged to have a high degree of efficacy, even in the setting of crusted scabies.

Benzyl Benzoate 10% to 25%.

Benzyl benzoate remains one of the most commonly prescribed agents for scabies in many parts of the world and compares favorably with other topical agents and oral ivermectin. Benzyl benzoate is not available in the US or Canada. The 25% emulsion is applied below the neck, with 3 applications during a 24-hour period. In young adults or children, the concentration can be reduced to 12.5%. Use can be complicated by allergic contact dermatitis, and benzyl benzoate should not be used during pregnancy, in lactating women, in infants, or in children younger than 2 years because of the risk for neurotoxicity.

Oral Ivermectin.

For the off-label treatment of scabies, ivermectin is given orally as a single dose of 200 μg/kg repeated in 7 to 10 days. High doses can cause embryotoxicity in animals, and some have suggested it should not be used during pregnancy, although ivermectin often has been used in this setting in the treatment of onchocerciasis. Safety has not been proved in children <15 kg (33 lb). Comparisons with permethrin, benzyl benzoate, and lindane have shown mixed results. In scabies-endemic areas, ivermectin has been shown to reduce the incidence of streptococcal disease and renal damage in children.[16,17]

Second-Line Treatments

Crotamiton 10%.

Crotamiton 10% is applied twice daily for 2 to 5 consecutive days. Although efficacy is low, crotamiton sometimes is used as an adjunctive agent because of its inherent antipruritic effect.

Special Considerations

Treatment of close contacts is strongly recommended; unfortunately, randomized controlled trials of treatment for contacts are lacking.[18] Crusted scabies may require treatment with both oral ivermectin and a topical agent. The author has found 10% precipitated sulfur to be most effective. Keratolytics should be used to improve penetration of treatment agents. The nails should be trimmed and brushed with a scabicidal agent. Patients with crusted scabies are highly infectious and require isolation.

Prevention

In some countries, soaps containing monosulfiram have been used for prophylaxis in communities with high rates of infestation.

Key Points

Diagnosis and Management of Scabies Infestation

Microbiology

- *Sarcoptes scabiei* var. *hominis* is an obligate human parasite and the usual agent of scabies.

Epidemiology

- Transmission occurs through close physical contact.
- Fomites such as bed sheets are an important means of spread in the setting of crusted scabies.

Treatment

- First-line treatments include permethrin, precipitated sulfur, benzyl benzoate, and oral ivermectin.
- Second-line treatments include crotamiton.

Duration of Therapy

- Most topical products should be applied twice, with a 7- to 10-day interval between treatments.

Babesia Species (Babesiosis)

Kristina N. Feja

Babesiosis is an emerging tickborne zoonotic disease, clinically similar to malaria, that is caused by intraerythrocytic protozoa in the genus *Babesia*.[1–10] Symptomatic infection is more frequently diagnosed and reported in asplenic adults,[11] those older than 50 years,[8] and immunocompromised hosts,[3,8] but neonates[12] and infants[13,14] also are infected in endemic areas after a tick bite, blood product transfusion,[14] and vertical transmission.[12,13] Although as many as 7 species of *Babesia* have been implicated in human babesiosis,[3] *B. microti* is most common in the northeastern and upper midwestern United States,[1] *B. duncani* in the western US,[15] and *B. divergens* in Europe.[2] Fever, malaise, and hemolytic anemia typify clinical disease,[16] which tends to be milder in *B. microti* infection[5] and more severe in *B. divergens* infection.[7] Clinical diagnosis is confirmed by identification of the parasite in a blood smear or detection of *Babesia* DNA in serum by polymerase chain reaction (PCR).[17] Atovaquone and azithromycin are considered the treatment of choice for mild to moderate disease.[18] Avoidance of exposure to the tick vector is the best measure to prevent babesiosis.[1]

Description of the Pathogen

Babesia spp. belong to the phylum Apicomplexa along with *Cryptosporidium, Plasmodium,* and *Toxoplasma*.[5] *Babesia* organisms require both a tick vector and a vertebrate host to complete their complex life cycle.[19] The parasites directly infect erythrocytes (without the pre-erythrocytic–hepatic stage that some plasmodia exhibit), where trophozoites divide by sporogony (budding) into two or four merozoites, depending on the species.[3,19,20] Egress of the merozoites occurs with lysis of the erythrocytes, leading to invasion of further red blood cells and clinical symptoms.[19,20] A more detailed description of the life cycle is presented at http://www.cdc.gov/parasites/babesiosis/biology.html.

Recent analyses of 18S ribosomal RNA sequence data[21] support division of human *Babesia* spp. into four clinically relevant clades.[3,6,20,21] Clade 1 contains *B. microti* and *B. microti*−like parasites; clade 2 includes *B. duncani*[15] (initially named WA1, WA2, CA5, and CA6) and *B. duncani*−like (CA1, CA3, CA4) organisms. Clade 3 comprises *B. divergens, B. venatorum* (previously designated EU1),[2,22,23] and *B. divergens*−like[4] cases. Clade 4 organisms are rarely transmitted to humans but include the human isolate from Korea (KO1).[24] Each *Babesia* sp. is transmitted by a certain *Ixodes* tick and has a primary vertebrate reservoir, whereas humans are accidental hosts. Nymphal ticks are the primary vector because of their small size and summer feeding activity,[5,25] but transmission of *B. microti* requires 36 to 72 hours of tick attachment.[26] Because these ticks also transmit *Borrelia burgdorferi* and *Anaplasma phagocytophilum,* coinfections occur.[27,28] The tick vector for *B. microti* in the eastern US is *Ixodes scapularis,* and the primary reservoir is the white-footed mouse.[3,5,20] Adult ticks feed on white-tailed deer, ensuring their survival, but the deer are not a reservoir for *B. microti*.[25] *B. divergens* and *B. venatorium* are both transmitted in Europe by *Ixodes ricinus*, and the primary reservoirs are cattle and roe deer, respectively.[3,5,20] The exact tick vectors for *B. duncani*, *B. duncani*−like, and *B. divergens*−like species are not established.[3] Transmission also occurs without the tick vector in congenital and perinatal[12,13,29–31] cases and during transfusion of blood from parasitemic donors.[14,32–34]

Epidemiology

Initially described as the cause of febrile hemoglobinuria in cattle in

1888,[35] *Babesia* are responsible for significant disease burden in livestock and animals.[3,19] The first human case was reported in a splenectomized male in 1957 in Europe,[36] and the first case in a healthy individual was reported in 1970 from Nantucket Island, Massachusetts (called *Nantucket fever*).[37] In the 1970s and 1980s, *B. microti* was found to be endemic in Massachusetts (Nantucket Island, Martha's Vineyard, Elizabeth Islands, and Cape Cod), Rhode Island (Block Island), southeastern Connecticut, and New York (Shelter Island, Fire Island, and eastern Long Island).[38] During the same period *B. divergens* caused sporadic but more severe disease in splenectomized adults in Europe.[7,39] During the past five decades the incidence of babesiosis in the US has increased substantially,[3,20,40–42] and with the recent use of molecular studies,[21] newly recognized species continue to emerge in ever-expanding geographic areas.[3,6,15,43]

National surveillance for human babesiosis in the US started in 2011, with required reporting in 18 states and New York City, and expanded to 27 states reporting in 2013.[44,45] A total of 1124 confirmed and probable cases of babesiosis were reported in 2011, 911 in 2012, and 1762 cases in 2013.[44–46] There appears to be underreporting in areas of emerging babesiosis, likely owing to lack of specific clinical signs (such as erythema migrans rash in Lyme disease) and low index of suspicion among medical providers.[47] In a study in New York state, 29% of patients serologically confirmed to have Lyme disease also were seropositive for *B. microti* compared with 7% without Lyme seropositivity, suggesting common co-infections.[48] Babesiosis is mostly seasonal, with about 85% of cases having symptom onset between June and August, when nymphal ticks are most actively feeding.[3,25] However, only 45% of patients recall a tick bite in the 8 weeks before symptom onset.[45] The mean age of reported US cases is consistently 62 years, and >60% are males.[44–46]

Currently, *B. microti* infection is endemic in the northeastern[38,40,49–53] and upper midwestern (Wisconsin[54] and Minnesota[55]) US, with >95% of cases consistently reported from 7 states (Connecticut, Massachusetts, Minnesota, New Jersey, New York, Rhode Island, and Wisconsin).[44–46] Community-based serosurveys in endemic areas of northeastern US performed in late 1970s to 1990s reveal antibodies to *B. microti* in 2% to 10% of residents,[41,42,56,57] whereas testing of blood-donor specimens from 2000 to 2012 in these same areas found antibodies in 1% to 1.4% of samples.[58,59] The incidence of babesiosis was 1620/100,000 on Block Island between 1991 and 2000 and 1250/100,000 on Nantucket Island in 2010.[41,47] The seroprevalence incidence in children (aged 0–19 years) on Block Island was 1632/100,000, slightly higher than the incidence among adults aged 20 to 89 years (1618/100,000).[41] In recent years, the spread of *B. microti* continues, with increased number of cases within endemic areas[41,50,60,61] and appearance of cases in contiguous areas such as Pennsylvania[62] and Canada[63,64] (Fig. 258.1) Although *B. microti* is the most common species in the US, rarely, *B. duncani* and *B. duncani*–type infections have been reported in Washington and California.[15,43,65] *B. divergens*–like infections have occurred in Missouri,[66] Kentucky,[67] and Washington State.[4,68]

In Europe, human babesiosis is much less common than in the US, with reported cases totaling <100.[2] Most cases result from *B. divergens* infection in asplenic individuals,[2,7,39,69] although cases in healthy persons have been reported.[70] Babesiosis has been reported in Croatia,[36] other eastern European countries, and western Europe,[71–75] including the United Kingdom, Ireland, and Scandinavia.[22,76–78] Few cases of disease due to *B. venatorum* (EU1) have been described.[23,73] Indigenous *B. microti* was first reported in Switzerland[22] and Germany,[79] but the disease likely is underrecognized and underreported owing to its less fulminant course and lack of cross-reactivity with serologic tests for *B. divergens*.[22] In Asia, cases of *B. microti*,[80,81] *B. venatorum*,[82] and a new strain (KO1) have been reported.[24] Human babesiosis also has been reported in Africa, Australia, and South America.[10,20,39,83,84] Further increase in the number of cases is expected with growing number of immunocompromised patients[3] and with the increase in tick vector populations linked to expanding deer populations[25,41,85,86] and climate change.[87]

Clinical Manifestations

Clinical manifestations of babesiosis vary from asymptomatic infection, to mild to moderate disease, to severe disease that can be fatal.[4] The incubation period following a tick bite is 1 to 4 weeks,[3] and 1 to 9 weeks (as long as 6 months) following transfusion.[25,88] Between 32% and 62% of infections are asymptomatic.[41,56,57,89] Infections can become symptomatic after many months of asymptomatic parasitemia.[89]

Clinical infection most often is a nonspecific, influenza-like illness, and the diagnosis is rarely made.[1,41] A gradual onset of malaise and fatigue is followed by fever as high as 40.5°C (105°F).[20] The most common symptoms of *B. microti* infection are summarized in Table 258.1. Additional symptoms reported in two series totaling 84 patients included emotional lability in 50%, neck stiffness in 48%, sore throat in 31%, vomiting in 20%, joint swelling in 11%, and conjunctivitis in 11%.[90,91] Individuals noted an average of 9 separate symptoms lasting 10 weeks.[90] Persistent parasitemia, as detected by PCR, can last for several months to >1 year, even with treatment.[89]

Disease-specific diagnosis of coinfecting tickborne zoonoses: babesiosis, human granulocytic ehrlichiosis, and Lyme disease. Clin Infect Dis 2002;34:1184–1191; and Krause PJ, Lepore T, Sikand VK, et al. Atovaquone and azithromycin for the treatment of babesiosis. N Engl J Med 2000;343:1454–1458.

Physical findings often are limited to fever in mild cases, although jaundice, pallor, mild hepatosplenomegaly, dark urine, and occasionally pharyngeal erythema can be present.[1,16,20] Noncardiac pulmonary edema[91] and ocular manifestations, such as retinal splinter hemorrhages, have been described.[92]

Typically, *B. divergens* and *B. divergens*–like infection is more fulminant,[7,20,39] resulting in a case-fatality rate of 42%.[3] However, *B. microti* also can cause severe disease, especially in those with risk factors, but mortality is <1%.[44] Risk factors for severe babesiosis, in addition to infection with *B. divergens,* include: age >50 years; male sex; asplenia[11]; and immune-compromising conditions,[93] including AIDS,[94] and malignancy.[1] Coinfection with *Borrelia* or *Anaplasma* spp., or both, appears to cause more severe disease[27,28,90,95]; therefore, any patient with prolonged or severe symptoms also should be tested for these pathogens.[1] About 45% of US patients with babesiosis require hospitalization for a median of 4 to 5 days.[44-46] Most hospitalized *B. microti*–infected patients have comorbidity, such as asplenia, heart disease, hypertension, chronic obstruction pulmonary disease, alcoholism, and diabetes.[16] Children aged 0 to 19 years have significantly fewer symptoms (40% are symptom free), have significantly shorter duration of illness, and are hospitalized infrequently, particularly compared with people older than 50 years.[41] Patients with anemia (hemoglobin concentration <10 g/dL) or parasitemia (>10%) are more likely to have complications,[16] such as acute respiratory distress syndrome, disseminated intravascular coagulopathy, congestive heart failure, acute renal failure, myocardial infarction,[16] splenic infarction,[96] splenic rupture,[97] septic shock,[98] and death.[75,77]

Laboratory Findings and Diagnosis

Laboratory findings can be normal or nonspecifically abnormal in asymptomatic or mild cases. Thrombocytopenia (mean around 90,000 cells/dL) and anemia (mean 10 g/dL) occur in >60% of patients.[16,45] Evidence of hemolysis (such as low hemoglobin and haptoglobin, elevated lactate dehydrogenase, and reticulocyte count), elevated serum hepatic transaminases (mean, 100−120 U/L), elevated blood urea level and creatinine, and variable leukocyte count can be present.[16,20,25]

Laboratory diagnosis of human babesiosis primarily employs Giemsa- or Wright-stained thin blood smear, PCR,[99] and species-specific serology.[17,100,101] Characteristic findings on blood smear are shown in Fig. 258.2. The tetrad of merozoites ("Maltese cross") is pathognomonic for *B. microti* and *B. duncani*, but is not seen commonly.[5,15] Blood smear findings for *Babesia* and *Plasmodium* are contrasted in Table 258.2. At least 300 microscopic fields should be reviewed because parasitemia levels can be <1% early in disease.[20] PCR testing is available in commercial laboratories, is more sensitive than blood smears, and is needed for accurate speciation.[1] Serologic testing most commonly is species-specific indirect immunofluorescence antibody assay and often is positive at the time parasitemia becomes detectable.[100] An enzyme immunoassay[58,102] and immunoblot testing[103] also are described. A fourfold increase of immunoglobulin G titers in acute and convalescent sera confirms recent infection.[25] A single positive titer supports the diagnosis, but is not confirmatory.[100] Diagnostic techniques are compared in Table 258.3.[104]

Overview of Diagnostic Approaches for Human Babesiosis

Diagnostic Method	Advantages	Disadvantages
Blood smear	Inexpensive, rapid; reliable with high parasitemia	Can be confused with malaria, especially by inexperienced reader; can be negative with low-level parasitemia
Immunofluorescent antibody assay (serology)	The only commercially available serology	Expensive; requires reference laboratory confirmation; cross-reactivity; species specific
Enzyme immunoassay (serology)	Less cross-reactivity	Not commercially available (investigational)
Hamster inoculation	Effective for low-parasitemia disease	Slow, labor intensive; can be negative with fastidious organisms
Microaerophilous	Effective for low-	Impractical for human disease diagnosis

stationary phase in vitro culture	parasitemia disease	
Polymerase chain reaction assay	Reliable; accurate if assay is standardized and performed well	Expensive

Modified from Schuster FL. Cultivation of *Babesia* and *Babesia*-like blood parasites: agents of an emerging zoonotic disease. Clin Microbiol Rev 2002;15:365–373.

Treatment

Asymptomatic patients with parasitemia (on blood smear or by PCR testing) do not need treatment unless they are parasitemic for >3 months.[1] Patients with mild to moderate disease should be treated with a 7- to 10-day course of atovaquone and azithromycin.[1,25,100] A randomized trial of quinine *plus* clindamycin therapy compared with atovaquone *plus* azithromycin therapy demonstrated equivalent cure rates, with significantly fewer toxicities in the latter group (15% vs. 72%).[105] Symptoms should improve after 48 hours of treatment.[1] Atovaquone and azithromycin therapy generally is well tolerated and successful in the treatment of infants,[12,106] but there are reports of drug resistance in immunocompromised persons (Table 258.4).[107]

TABLE 258.4

Treatment Regimens for Human Babesiosis

Drug	Adult Dose	Pediatric Dose[a]
ATOVAQUONE *PLUS* AZITHROMYCIN		
Atovaquone (oral)	750 mg every 12 hr	20 mg/kg/dose every 12 hr
Azithromycin (oral)[b]	500–1000 mg once on day 1, then 250 mg daily	10 mg/kg/dose once on day 1, then 5 mg/kg/dose once daily
CLINDAMYCIN *PLUS* QUININE		
Clindamycin (intravenous)	300–600 mg every 6 hr	7–10 mg/kg/dose every 6–8 hr
Clindamycin (oral)	600 mg every 8 hr	7–10 mg/kg/dose every 6–8 hr
Quinine (oral)[c]	650 mg every 6–8 hr	8 mg/kg/dose every 8 hr

[a] Maximal pediatric doses should not exceed adult doses

[b] In immunocompromised patients higher doses of 600−1000 mg/day may be used.[1]

[c] Intravenous quinidine can be used in place of oral quinine if patient is monitored in hospital for possible QT prolongation.[25]

Severe illness should be treated with 7 to 10 days of quinine *plus* clindamycin intravenously.[1] In addition to supportive care, exchange transfusion (which greatly reduces the level of parasitemia) is indicated in severe cases with high-grade parasitemia (≥10%), significant hemolysis, or renal, hepatic, or pulmonary compromise.[1] Although routine screening of healthy individuals for posttreatment relapse is not recommended, those found to have positive thin blood smears or PCR positivity for >3 months after completing therapy should be retreated, irrespective of symptoms.[1] Immunocompromised patients can develop persistent or relapsing disease; therefore these patients should be monitored for recurrence of symptoms and have thin blood smears or PCR checked only if symptoms arise.[93] Other agents used in this population, often in combination, for multiple and prolonged courses, include atovaquone, azithromycin, clindamycin (intravenous route is preferred[1]), doxycycline, proguanil, pentamidine, quinine, and trimethoprim-sulfamethoxazole.[93] Continuation of treatment for at least 6 weeks total and for at least 2 weeks beyond clearance of parasitemia by thin blood smear is associated with more frequent cure.[93,108] No adjunctive immunomodulating therapies have been identified.

Special Considerations

Immunocompromised hosts, such as asplenic individuals, are at particular risk for severe *Babesia* infection, mostly due to *B. divergens*, but also to *B. microti,* although the disease usually is less severe than with *B. divergens*.[3,7,11,93] In those with AIDS, babesiosis can manifest as fever of unknown origin as well as persistent or relapsing disease.[94] An underlying immunodeficiency should be considered in any patient with severe or prolonged babesiosis.[1] Transfusion-associated babesiosis is an emerging problem[32–34] and currently is the most frequent transfusion-transmitted infection, with >170 cases reported since 1980.[25,109] Transplant recipients[95] and neonates[14,32,110–112] are frequently affected. There is no US Food and Drug Administration–approved method for laboratory screening of the blood supply. Instead, potential donors with a history of babesiosis are permanently denied from (and should decline) donating. Preliminary data from the first laboratory-based blood donor screening program using immunofluorescence antibody and

PCR eliminated transmission to neonates and pediatric hemoglobinopathy patients.[113] Enzyme immunoassay appears best suited for efficient high-throughput blood donor screening.[58] Although two cases of tick-transmitted babesiosis in neonates were reported from Long Island,[114] most cases in neonates are transfusion associated.[14] To date, 5 cases of congenital or perinatal babesiosis have been reported.[12,13,29–31]

Prevention

The best way to prevent babesiosis is to avoid exposure to ixodid ticks.[1] If exposure to the vector is unavoidable, wearing protective clothing (long pants, tucked into socks or boots, and long sleeves), use of tick repellants, daily careful examination of the entire body for ticks, and prompt removal of ticks can decrease the likelihood of being bitten or having infection transmitted during a bite.[1] Careful observation for development of symptoms for a month or so after tick removal is prudent, but there is no role for antibiotic prophylaxis, examination of removed ticks for parasites, or laboratory testing of asymptomatic individuals after tick removal.[1] Screening the blood supply and decreasing infections during pregnancy also can prevent babesiosis.[17] Although animal vaccines exist, there is no role for passive or active immunoprophylaxis in humans. Aside from transfusion-associated (and, potentially, organ-associated)[95] transmission, no human-to-human transmission has been documented, and no particular infection prevention measures are necessary.

The author acknowledges the substantial use of Robert W. Tolan's work from the previous edition and expresses sadness of the infectious diseases community over his untimely loss.

Key Points

Diagnosis and Management of *Babesia* species (Babesiosis) Infection

Microbiology

- Apicomplexan intraerythrocytic parasite transmitted to humans by ixodid tick bites
- The same vector transmits *Borrelia burgdorferi* and *Anaplasma phagocytophilum*.
- *Babesia microti* most common in United States; *Babesia divergens* in Europe; other species much less common

Epidemiology

- Most case of *B. microti* in the US occur in CT, MA, MN, NJ, NY, RI, WI.
- Sporadic cases in CA, IN, KY, MD, MO, VT, WA in the US as well as in Europe and worldwide
- Range of endemicity is expanding rapidly.
- Chief risk factors are age >50 years, asplenia, male sex, and immunocompromising conditions.
- Transfusion-transmitted infection is recognized increasingly.
- Congenital/perinatal transmission is rare but is well documented.

Diagnosis

- Thin blood smear microscopy is rapid, inexpensive, and diagnostic with appropriate expertise.
- Speciation requires polymerase chain reaction (PCR) testing.
- Serology can support clinical suspicion but is suboptimal for management decisions.

Treatment

- Asymptomatic infection requires no treatment unless parasitemia lasts >3 months.

- Atovaquone *plus* azithromycin combination is preferred treatment for most cases.

- Quinine *plus* intravenous clindamycin along with exchange transfusion is preferred treatment for severe cases

Duration of Therapy

- Prolonged parasitemia (>7 days) can occur despite clinical improvement.

- Duration of therapy typically is 7 to 10 days for the immunocompetent host.

- In the compromised host, therapy should continue for 2 weeks after negative thin blood smears and negative PCR, or for 6 weeks (whichever is longer).

Balantioides coli (Formerly *Balantidium coli*)

Kateřina Jirků-Pomajbíková, Christen R. Stensvold

Balantioides coli originally was called *Balantidium coli*, syn. *Neobalantidium coli*, but recently has been renamed based on new phylogenetic observations.[1,2] This cosmopolitan ciliate inhabits the intestine of several mammalian species, and it is the only ciliate known to infect humans.[3] Balantiosis is considered a neglected zoonotic disease, and human clinical cases are typically associated with close contact with domestic pigs.[3] Infected people can be symptom free or may develop symptoms, ranging from mild diarrhea to fulminating dysentery.[4]

Life Cycle and Description

The life cycle of *B. coli* comprises two stages: the motile trophozoite that inhabits the host's hindgut and causes disease, and the cyst that is environmentally resistant and is responsible for transmission (Fig. 259.1).[3] Trophozoites are large and ovoid, measuring 50 to 150 µm. The cytostome is visible at the anterior end of the body, and a kidney-shaped macronucleus and longitudinal cilia rows on the surface are often visible.[3–5] The cytoplasm may contain ingested particles in contractile vacuoles (Fig. 259.2).[5] The cyst is spherical and thick-walled, with a size ranging between 40 and 60 μm and with a visible trophozoite inside.[3–5] The cyst stage is commonly detected in pig feces, but rarely in human or nonhuman primate feces (Fig. 259.3).[3,6,7]

Epidemiology

B. coli is zoonotic, occurs worldwide, and has been found in several mammalian hosts such as humans, captive African great apes, domestic pigs, and wild boars.[1,3,4] Suid infections are usually not linked to any pathologic manifestations, and suids are considered reservoir hosts, being a source of infection for humans.[3,8] It is not unusual for the prevalence of *B. coli* in populations of suids to reach 100%.[3,9] Balantiosis is considered a waterborne and foodborne disease, which means that water and food contaminated with cysts can be a source of infection.[3,10,11]

Although human infections have been reported from most parts of the world, there is high prevalence in some tropical and subtropical areas, including New Guinea, southern Iran, South and Central America, central Asia, the Philippines, and some Pacific islands.[3,12] In Papua New Guinea, where common domestic animals include pigs, the prevalence in humans may be up to 28%.[13,14] In Peru, 6% of a study cohort was found to be infected with *B. coli,*[15] and in 11 of 22 Bolivian Altiplano communities surveyed, *B. coli* prevalence ranged between 1% and 5%.[16] In the United States and other economically developed countries, sporadic infections have been reported in disabled people living in institutions where poor conditions of personal hygiene prevail.[17] Human infection is rare in industrialized countries but can occur in susceptible (e.g. immunocompromised) individuals.[18,19]

Clinical Manifestations

Humans infected with *B. coli* can be symptom free, but under certain circumstances, *B. coli* trophozoites can invade the mucosa of the cecum and colon, causing balantiosis. In such cases, clinical manifestations take two main forms: diarrhea and dysentery (Fig. 259.4).[3] The disease usually is chronic with intermittent episodes of diarrhea of varying severity and constipation associated with abdominal pain, anorexia, weight loss, and weakness.[3] Sometimes, symptoms in the cecal region mimic appendicitis. The differential diagnosis includes amebic and bacterial dysentery as well as noninfectious disorders (e.g., inflammatory bowel disease).[5] Rarely, *B. coli* trophozoites perforate the intestinal wall by penetrating through the muscular layers into the peritoneal cavity.[18–21] Extraintestinal infections of the liver, lungs, and genitourinary tract have been reported.[18,22,23] In most people, recovery occurs without treatment, but in malnourished or immunosuppressed hosts, the disease course can be fulminant and fatal.[18,24] *B. coli* should be considered in immunocompromised people with diarrhea.[18,22–24] Factors predisposing to clinical illness include malnutrition, alcoholism, hypochlorhydria, and other causes of immunosuppression (e.g., malignancies or HIV).[3] Moreover, recently it was revealed that a diet rich in starch might predispose hosts to developing balantiosis.[25]

Diagnosis

The diagnosis usually is made by visualizing cysts or trophozoites, or both, in a fecal specimen, in scrapings obtained from inflamed gut mucosa, or in an endoscopic biopsy collected from the periphery of ulcers. *B. coli* is commonly diagnosed by coprologic methods (e.g., wet mounts, flotation, concentration, or staining techniques), but merthiolate-iodine-formaldehyde sedimentation is recommended as the gold standard because of its high sensitivity for both trophozoites and cysts.[3,4] Samples usually are examined using light microscopy; a phase contrast microscope can be used to help identify *B. coli* morphologic features.[3] The cyst stage is detected in the feces of suids, whereas the trophozoite stage typically is found in human and ape feces.[4] Because trophozoites disintegrate rapidly in feces, fecal samples must be examined as soon as possible after collection or be placed in fixation medium such as 4% formaldehyde (only for coprologic examination) or 96% ethanol (also for molecular analyses).[1,3,4]

Treatment and Prevention

Tetracycline, which should not be given to pregnant women and children younger than 8 years, is the drug of choice.[26,27] Tetracycline (for adults 500 mg orally 4 times daily for 10 days; contraindicated for children younger than 8 yrs and for pregnant women) is effective. Alternative therapies include metronidazole (for adults, 500–750 mg orally 3 times daily for 5 days; for children, 35–50 mg/kg/day orally in 3 dosage for 5 days), or iodoquinol for adults, 650 mg orally 3 times daily for 20 days; for children, 30–40 mg/kg/day [maximum, 2 g] orally for 20 days).[26,27] For more information on the treatment of balantidiasis, see the Centers for Disease Control and Prevention web page https://www.cdc.gov/dpdx/balantidiasis/tx.html.

To reduce transmission, prevention of contamination of the environment with pig feces is important. Reducing human contact with infected pigs and with contaminated food and water and improving conditions of personal hygiene and nutrition are additional methods of control.

Blastocystis

Christen R. Stensvold

Blastocystis is a protist parasitizing the lower intestine of humans and a vast range of animals. Although *Blastocystis* has been implicated as a cause of various gastrointestinal tract symptoms, its role as a pathogen, mechanism of transmission, and life cycle have been subject to much debate.[1–4] A clinical syndrome of self-limited intestinal symptoms has been described in several series of predominantly adult patients, with infection intensity possibly accounting for differences in clinical presentation.[5] Extraintestinal manifestations, such as urticaria, also have been described.[6,7] *Blastocystis* spp. from humans, other mammals, and birds are classified into subtypes, but because non–DNA-based laboratory methods do not enable distinction between subtypes, the organism should be reported as *Blastocystis* sp. not as *Blastocystis hominis*.[8]

Organism

Blastocystis is a protist belonging to the Stramenopiles.[9] It has been isolated from a wide variety of animals and has been reported in human populations from most parts of the world.[10] A total of 9 subtypes (arguably species) have been identified in humans to date, with humans colonized most commonly by subtypes 1, 2, 3, and 4, depending on geographic region.[8,10,11] Several morphologic stages have been described, including the vacuolar, avacuolar, multivacuolar, granular, ameboid, and cystic stages. The vacuolar form is observed most frequently in clinical samples and in fecal cultures; it is spherical and usually ranges in size from 4 to 15 μm in diameter[12]; much larger cells may be seen in cultures. The cyst (2–5 μm) is the transmissible form and is able to survive in water at room temperature for up to 19 days but is fragile at extremes of heat and cold and when exposed to common disinfectants.[13–16] After ingestion of an infectious cyst, the organism excysts in the lumen of the cecum and proximal colon, developing into vacuolar forms and undergoing encystation before being excreted as the cyst form, which, if eaten, completes the cycle.

Epidemiology

Blastocystis has a global distribution. Surveys of intestinal parasites in population groups in developing countries documented prevalence rates of 54% in Papua New Guinea and 33% among travelers and foreign residents with diarrhea in Nepal.[17,18] In a study of fecal specimens from 48 states and the District of Columbia, *Blastocystis* was identified in 23% of 5792 stool specimens.[19]

There are few reports of *Blastocystis* infection in children. A study surveying 1042 internationally adopted children submitting at least one stool specimen for ova and parasite testing within 120 days after arrival to the United States saw a prevalence of *Blastocystis* of 10%.[20] A community-based survey northeast of Mexico City reported a frequency of 7% in children younger than 14 years.[21] A study of the prevalence of enteroparasites in a facility for orphaned and homeless children in Argentina found *Blastocystis* in 44% of stool samples.[22] A similar study of children living in residential institutions and street communities in metropolitan Manila, Philippines found *Blastocystis* in 41% of children examined.[23] A community-based study in Papua New Guinea found that >65% of children younger than 18 years had *Blastocystis.*[17] Meanwhile, the use of DNA-based diagnostic methods recently led to identification of a 100% prevalence in Senegalese children with gastrointestinal symptoms.[24]

Infection has been associated with recent travel to the tropics and consumption of untreated water.[25,26] *Blastocystis* has been detected in cases of nosocomial diarrhea and in children attending childcare centers.[27,28] Sexually active homosexual men have *Blastocystis* infection rates as high as 52%, a finding consistent with person-to-person transmission.[29] Limited data suggest that illness due to *Blastocystis* can be more severe in patients with AIDS and other immunocompromising disorders.[30,31] Working with animals may increase the risk for becoming infected with *Blastocystis*.[32]

Clinical Manifestations

Whether *Blastocystis* causes disease is controversial, and potential mechanisms of pathogenicity is unclear. Symptoms described in *Blastocystis*-positive individuals include abdominal pain, diarrhea, nausea, anorexia, bloating, and flatulence. Means to differentiate infection from colonization do not exist.[1] Differences in clinical presentation might be due to one or more of the following factors: subtype virulence factors, immune status of the host, host genotype, parasite load, host response, and dysbiosis.[1] Nevertheless, the presence of this organism in stool suggests that the host was exposed to fecally contaminated food or drink. *Blastocystis* does not appear to be more common in patients with inflammatory or functional bowel diseases than in healthy individuals, although conflicting data exist.[33–35]

Attempts to infect germ-free guinea pigs did not provide convincing evidence of pathogenicity, except when large numbers of organisms were inoculated with normal enteric flora, with gross pathologic effects being limited to mild intestinal hyperemia.[36] Microscopic examination revealed a slight increase in cellularity and intraepithelial penetration by *Blastocystis.* A case-control study examining the association between acquisition of *Blastocystis* and presence of mucosal lesions by upper gastrointestinal endoscopy and sigmoidoscopy failed to demonstrate intestinal pathology.[37] Studies on *Blastocystis* in a gut microbiota context are emerging, and it is possible that such studies hold the key to unraveling the clinical significance of *Blastocystis*.[38]

Diagnosis

Diagnosis most often is made by staining of a fixed fecal specimen with iron hematoxylin or trichrome stain (Fig. 260.1), which is superior to iodine staining of wet mounts and microscopy of fecal concentrates.[39,40] Recognition of the organism can be difficult because of large variation in size and form. *Blastocystis* can be grown readily in culture using Jones medium, with relatively high diagnostic sensitivity.[39,41] Polymerase chain reaction testing is both highly sensitive and specific, but is used primarily for research.[41,42] Studies using serology are scarce, and it is not known whether serology could be a useful tool to distinguish infection from colonization.

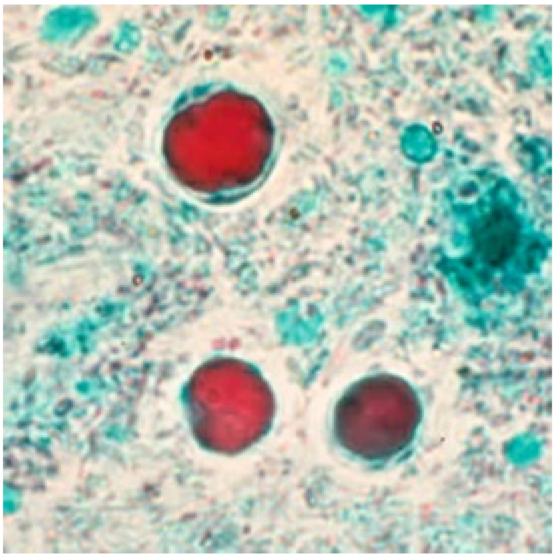

FIGURE 260.1 Vacuolar forms of *Blastocystis* in a fixed fecal smear stained with trichrome stain (Courtesy of DPDx image library, Centers for Disease Control and Prevention).

Treatment and Prevention

Detection of the organism in feces should not lead automatically to administration of antimicrobial therapy because clinical significance is controversial and carriage is common; most children in whom *Blastocystis* is detected should not be treated. Therapy should be considered in cases of persistent intestinal symptoms and when no other cause is found. Metronidazole alone, which often is used for *Blastocystis* eradication, appears to have very limited effect, whereas other drugs, such as paromomycin, nitazoxanide, and so-called triple therapy (diloxanide furoate, trimethoprim-sulfamethoxazole, and secnidazole) might be somewhat efficacious.[43–45]

Prevention of *Blastocystis* infection involves adequate sanitation, careful handwashing, avoidance of untreated water, and use of enteric precautions to interrupt person-to-person spread.

Cryptosporidium Species

Mohammed Nael Mhaissen, Patricia M. Flynn

Human disease caused by *Cryptosporidium* was first described in 1976 and became recognized increasingly during the human immunodeficiency virus (HIV) epidemic. Improved detection of oocysts in feces has shown *Cryptosporidium* to be a common cause of diarrhea in both immunocompetent and immunocompromised hosts.[1,2] In developing countries, *Cryptosporidium* is among the four most common causes of moderate to severe diarrhea and diarrhea-associated deaths in young children.[3]

The Pathogen

Organisms of the genus *Cryptosporidium* are 2- to 6-µm coccidian parasites that infect epithelial cells lining the digestive and respiratory tracts of vertebrates, including fish, birds, reptiles, and mammals as well as humans. The organism lacks host specificity; however, most human infections are caused by *Cryptosporidium hominis* or *C. parvum*.[4–6] The life cycle of *Cryptosporidium* is similar to that of other true coccidia that infect mammals. Infectious oocysts excyst within the lumen of the intestine and release sporozoites. The released sporozoites penetrate host cells, where they develop into trophozoites. Trophozoites can undergo asexual division resulting in autoinfection in adjacent cells or undergo sexual reproduction resulting in formation of oocysts. After fertilization of gametes, a thick-walled oocyst is formed. The oocysts of *Cryptosporidium* undergo sporogony within the host cells and are infectious when released in feces.[4]

Epidemiology

Oocysts of *Cryptosporidium* withstand adverse environmental conditions and can survive for long periods if stored moist and cold.[7] Oocysts are resistant to common disinfectants, including disinfectants recommended for hospital use. One study found that ammonia concentrations of >50% and formalin concentrations of ≥10% were necessary to kill the organism.[8]

Infection occurs after ingestion or, possibly, inhalation of infectious spores.[9] In healthy adult volunteers with no serologic evidence of past infection with *C. parvum,* the median infective dose was 132 oocysts.[10] Spread to humans occurs through person-to-person transmission and from ingestion of environmentally contaminated water or contaminated food.[4,11–13] An increase in cases reported in 2007–2008 is attributable partially to multiple large recreational water-associated outbreaks.[14] Transmission also has been linked with close association with infected animals.[15,16] Person-to-person transmission is responsible for cryptosporidiosis outbreaks in childcare centers and hospitals and is most often caused by *C. hominis*.[17] *Cryptosporidium* also causes traveler's diarrhea.[4] In the United States, reported cases of cryptosporidiosis are highest among young children (ages 1-4 years) with an estimated incidence rate of 6.6 per 100,000 population during 2011–2012. Symptoms peak in the summer and early fall (June through October), coinciding with the summer recreational water season.[18,19]

Zoonotic transmission from calves has been well documented, and other animals such as rodents, puppies, and kittens probably also serve as reservoir hosts.[4,20] Zoonotic transmission occurs in people living and working in close association with animals and is most often caused by *C. parvum*. A recent review of the waterborne parasitic outbreaks reported worldwide between 2004 and 2010 found that *Cryptosporidium* spp. were the etiologic agent in 60% of the outbreaks.[21]

Outbreaks of cryptosporidial infection have been associated with contaminated community water supplies in several US states and the United Kingdom.[22,23] In 1993, a waterborne outbreak in Milwaukee, Wisconsin caused approximately 400,000 cases of diarrhea.[23] Consumption of untreated surface water or inadequate water filtration has occurred in some waterborne outbreaks. Swimming pool water and water from decorative fountains have been linked to outbreaks.[18] An accidental fecal spillage into a community swimming pool resulted in 44 persons contracting diarrhea in one outbreak. Attack rates in different groups of swimmers ranged from 47% to 100% of exposed group members, with the highest rate in people with prolonged water exposure.[22] Waste water in the form of raw sewage and runoff from dairies and grazing lands can contaminate drinking and recreational water.[4,18] Molecular techniques allow specific linkages of outbreaks of *Cryptosporidium* disease to human versus animal contamination of water.[5]

Cryptosporidiosis is associated with diarrheal illness worldwide but is more prevalent in underdeveloped countries and in children younger than 2 years.[2,4,24–26] Surveys of selected populations have shown that infection rates in developed countries range from 0.6% to 20% compared with rates as high as 32% in less developed countries.[27] Seroprevalence studies confirm that cryptosporidiosis is more common in developing countries. In Europe and North America, approximately 25% to 35% of people have antibodies against *Cryptosporidium,* compared with 64% in Peru and Venezuela.[4] Increased infection rate probably is due to poor sanitation, lack of clean water, crowded living conditions, and close association with animals.[4]

Clinical Manifestations

Cryptosporidiosis is characterized by profuse watery diarrhea that can contain mucus but rarely contains white or red blood cells. Fifty percent of affected people have crampy abdominal pain, nausea, and vomiting. Nonspecific symptoms such as myalgia, fatigue, weakness, headache, anorexia, weight loss, and low-grade fever also may occur as well as asymptomatic infection.[4,7,17,27–29] Severity of symptoms correlates with density of oocyst shedding, which can be intermittent. Symptoms may vary based on the species of infecting *Cryptosporidium*.[30] Malabsorption, lactose intolerance, dehydration, and malnutrition often occur in severe cases. Radiographic findings are nonspecific and include prominent mucosal folds and thickening of intestinal walls.[7]

The incubation period is 2 to 14 days. Infection can be asymptomatic, self-limited, or protracted with severity linked to immunosuppression. Most immunocompetent hosts have a self-limited diarrheal illness that usually resolves within 10 to 14 days, although diarrhea can persist for as long as 5 weeks.[31] Oocyst shedding can continue for up to 2 weeks after clinical improvement.[23] Prolonged, debilitating disease can occur in immunocompromised hosts, including people with HIV infection, malignancy, CD40 ligand deficiency, severe combined immunodeficiency syndrome, other T-lymphocyte abnormalities, or selective immunoglobulin A deficiency and in solid-organ or stem cell transplant recipients, patients with end-stage renal disease undergoing hemodialysis, or people who are undernourished.[6,32]

Biliary tract disease is well documented in immunocompromised hosts and is characterized by fever, right upper quadrant pain, nausea, vomiting, and diarrhea. Jaundice and elevated serum levels of alkaline phosphatase, γ-glutamyltranspeptidase, and bilirubin can occur. The gallbladder can appear dilated and thick-walled on radiography and ultrasonography. If stenosis of the common bile duct occurs, the extrahepatic ducts usually are dilated.[33] Approximately 15% of patients with the acquired immunodeficiency syndrome (AIDS) who have cryptosporidiosis have biliary tract involvement. *Cryptosporidium* also has been detected in the pancreatic duct of a child with AIDS and has been associated with pancreatitis and sclerosing cholangitis in an immunocompetent host.[4,7,27,33,34]

Cryptosporidium has been detected in people with respiratory tract symptoms including cough, shortness of breath, wheezing, croup, and hoarseness. These symptoms can occur with and without diarrhea. Oocysts have been identified in sputum and bronchoalveolar lavage specimens. Not all respiratory tract symptoms can be attributed to cryptosporidiosis because other pathogens often are present, especially in HIV-infected patients. Further study of respiratory tract disease, including the potential for airborne spread of the organism, is warranted.[4,9,35]

Laboratory Diagnosis

Most clinical laboratories use enzyme immunoassays or immunofluorescence assays to detect *Cryptosporidium* antigens in stool specimens. Polymerase chain reaction analysis also has been reported to have an increased sensitivity over light microscopy and is now considered the diagnostic method of choice.[36–38] In addition, polymerase chain reaction may be beneficial as an epidemiologic tool.

The definitive diagnosis of cryptosporidial infection relies on identifying oocysts in feces or body fluids, or along the epithelial surface of biopsy tissue (Fig. 261.1). On sections stained with hematoxylin and eosin, oocysts appear as small, spherical, basophilic bodies located along the microvilli of the epithelium lining of the gastrointestinal tract. Because not all areas of the intestinal tract may be affected, sampling errors can occur. An indirect immunofluorescence assay can be used to detect oocysts in embedded tissue.[4] Histologic sections reveal villous atrophy and blunting, epithelial flattening, and inflammation of the lamina propria.

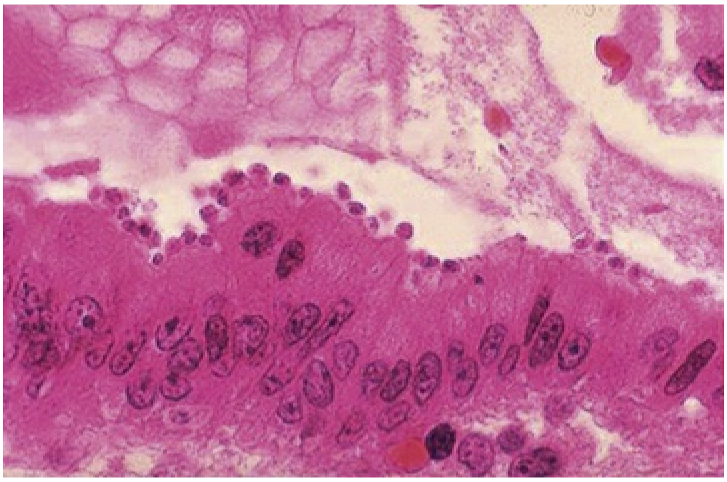

FIGURE 261.1 Cryptosporidia can be seen along the luminal border of the small bowel.

Fresh stool specimens should be placed in a fixative before submission to the laboratory, to prevent infection of laboratory workers. At least three specimens should be examined in immunocompetent hosts and two specimens in immunocompromised hosts.[39] Serodiagnostic assays are available for epidemiologic study; however, the role of serodiagnosis in acute diarrheal disease is undefined.[4]

Treatment

In most immunocompetent hosts, cryptosporidiosis is self-limited and requires no therapy except maintenance of adequate hydration. In severe cases, including immunocompromised hosts, a variety of antimicrobial agents have been used with no consistent success. Nitazoxanide is the only approved therapy for cryptosporidiosis and is approved for this condition in children. Clinical trials have demonstrated reductions in duration of diarrhea and oocyst shedding after treatment.[40–43] However, in studies of HIV-infected children in Zambia, nitazoxanide, including prolonged high-dose therapy, did not appear to be beneficial.[42,44] The recommended dose is 200 mg twice a day for 3 days for children 4 through 11 years of age, and 100 mg twice a day for children 12 through 47 months of age. The dose of nitazoxanide in people ≥12 years of age is 500 mg twice a day for 3 days.

Clarithromycin, azithromycin, roxithromycin, and paromomycin, a nonabsorbable aminoglycoside, have been reported to be successful in managing cryptosporidial diarrhea in immunocompromised patients.[45–53] However, randomized trials show conflicting results.[49,52,53] Combination therapy with paromomycin and azithromycin has been proposed, but limited clinical experiences preclude recommendations.[54]

Immunologic therapy may be beneficial in patients with cryptosporidiosis. Breastfeeding may be protective.[55] Oral administration of hyperimmune bovine colostrum, dialyzable leukocyte extract (a cell-free supernatant from the lymph nodes of immunized cows), and human serum immune globulin have all been reported to attenuate diarrhea and other symptoms associated with cryptosporidiosis.[28,56,57]

In addition to specific antiparasitic agents, use of nonspecific antidiarrheal agents such as kaolin plus pectin, loperamide, diphenoxylate, bismuth subsalicylate, or opiates have been helpful in management of symptoms, as well as the long-acting parenteral somatostatin analogue octreotide acetate.[28]

Special Considerations

HIV-infected people have high rates of cryptosporidial infection. Before the availability of combination antiretroviral therapy (cART), about 10% to 15% of AIDS patients in the US had reported cryptosporidiosis, whereas the prevalence in developing countries, such as in Haiti and countries in central Africa, is as high as 50%. Infections in HIV-infected people can be self-limited or chronic; rarely, asymptomatic infection can occur. A retrospective review indicated that patients with CD4$^+$ T-lymphocyte counts of >180 cells/mm^3 often have spontaneous resolution of infection. In patients with more severe immunosuppression, chronic disease is likely to develop.[58] Improvements in symptoms and clearance of shedding of oocysts can occur after treatment with cART, and most experts recommend starting cART in treatment-naïve patients with *Cryptosporidium* infections.[35,59] This may be due to improvement in the immune system as well as some effect of protease inhibitors on the parasite's life cycle.[60]

Outbreaks of *Cryptosporidium* infection in childcare centers are reported with increasing frequency.[61–63] Childcare centers with toddlers most often are involved, and the attack rate can be as high as 67%.[62] In addition, family members have been infected by attendees.[64] Transmission of infection within closed pediatric hospital units also has been documented.[65]

Prevention

Because the organism most commonly is spread by person-to-person transfer, handwashing helps prevent infection. Alcohol-based hand cleaners are not effective against *Cryptosporidium* spp.[18] Universal precautions should be used for hospitalized patients older than 6 years; diapered or incontinent children younger than 6 years should be managed with contact precautions. Infected people in hospitals can be cohorted to limit the spread of disease. Children with diarrhea should not attend group childcare. Immunocompromised people should take special precautions around animals. People should avoid swallowing recreational water; avoid drinking water from shallow wells, lakes, rivers, streams, ponds, and springs; and avoid drinking untreated water during community-wide outbreaks caused by contaminated drinking water.[16]

Key Points

Diagnosis, Clinical Features, and Treatment of Cryptosporidiosis

Microbiology

- Most infections are caused by *Cryptosporidium hominis* or *C. parvum*, 2- to 6-µm coccidian parasites that infect epithelial cells lining the intestinal and respiratory tracts.
- Oocysts are infectious when released from the infected host.

Epidemiology

- Infection occurs through person-to-person transmission, from ingestion of environmentally contaminated water or contaminated food, and through zoonotic transmission.
- Outbreaks have been associated with contaminated community water supplies, swimming pool and recreational water exposure, and childcare center attendance.

Clinical Features

- Profuse watery diarrhea without white or red blood cells is most common.
- Infection also can be associated with myalgia, fatigue, weakness, headache, anorexia, weight loss, and low-grade fever; asymptomatic infection can occur.
- Symptoms are more severe in immunocompromised hosts.

Diagnosis

- Polymerase chain reaction, enzyme immunoassays, or immunofluorescence assays on stool specimens, or identification of oocysts in feces

- Multiple samples improve sensitivity of testing.

Treatment

- Self-limited in immunocompetent hosts
- Nitazoxanide is the only approved therapy.
- In HIV-infected patients, treatment of HIV with combination antiretroviral therapy may improve clinical symptoms.

Endolimax nana

Casper S. Poulsen, Christen R. Stensvold

Endolimax nana is a single-celled parasite of the colon. Although considered nonpathogenic, infection with *E. nana* is an indicator of exposure to fecal contamination and often is seen in fecal samples positive for other common parasitic intestinal protists.

Description of *Endolimax nana*

E. nana is an intestinal parasitic ameba, which appears to be most closely related to *Iodamoeba*.[1,2] *E. nana* has a monoxenous life cycle (Fig. 262.1), with trophozoite stages (8–10 μm) found in the colon where they move by pseudopodia, feeding exclusively on bacteria.[3,4] The trophozoite nucleus is vesicular and spherical with a polymorphic karyosome (Fig. 262.2). After encystation, the oval cyst (6–9 μm × 5–7 μm) is excreted in feces, and when mature, it contains four nuclei (Fig. 262.3). Mature cysts may excyst and colonize the colon when ingested.[3–5] When established, the ameba may persist in the colon for up to at least 17 years.[4]

Epidemiology and Clinical Manifestations

E. nana has a worldwide distribution and has commonly been associated with cases of diarrhea in children; this association may be explained in part by *E. nana* being an indicator of fecal contamination of food or water.[6–8] In general, *E. nana* is highly prevalent in children from developing countries such as Cote d'Ivoire (83%), Brazil (43%), Nicaragua (35%), and Thailand (8%).[9–12] A lower prevalence (1.5%) was reported in a survey from Germany (2%).[13]

Diagnosis and Treatment

Detection of *Endolimax* traditionally relies on microscopy, with trophozoites and cysts being identifiable by direct examination. The formalin-ether concentration method is routinely used, and when stained with iodine, the oval cysts may appear gibbous with the four nuclei paired and located at each end.[4] However, cysts and trophozoites are difficult to differentiate from other amebas, such as *Entamoeba histolytica, Entamoeba hartmanni*, and *Dientamoeba fragilis*. It is especially difficult to differentiate between cysts of *E. hartmanni* and *E. nana* because they are similar in size and have four nuclei; however, *E. nana* nuclei have a larger punctuate karyosome and lack peripheral chromatin, but high magnification (oil lens; original magnification, ×1000) is needed to discern these features with confidence. Because *E. nana* is considered a commensal, treatment usually is not recommended.

Entamoeba histolytica (Amebiasis)

Joanna Nelson, Upinder Singh

Entamoeba histolytica is a tissue-lysing ameba that typically causes colitis or liver abscess. It was first discovered in 1875 by Fedor Aleksandrovich Lösch, who described amebic trophozoites in the stool and colonic ulcerations in a farmer with a fatal case of dysentery.[1] In 1993, what was once thought to be a fairly ubiquitous parasite was reclassified into two morphologically identical but genetically distinct species: the pathogenic *Entamoeba histolytica*, an invasive disease-causing parasite; and the commensal *Entamoeba dispar*, a noninvasive parasite.[2]

Description of the Pathogen

E. histolytica is a pseudopod-forming, nonflagellated protozoan parasite. Historically, it was considered the only invasive species of parasites in the *Entamoeba* genus infecting humans (including *E. histolytica, E. dispar, E. moshkovskii, E. hartmanni, E. polecki, E. coli, E. gingivalis, E. chattoni,* and *E. bangladeshi*). However, recently *E. moshkovskii* and the newly discovered *E. bangladeshi* have been associated with diarrhea in children.[3–5] Molecular phylogeny of eukaryotic organisms based on small subunit ribosomal RNA places *Entamoeba* on the lowermost branches of the eukaryotic tree, closest to the social ameba *Dictyostelium discoideum,* whereas analysis of elongation factor 1α shows that *E. histolytica* is likely an outgroup of *Euglena* and higher eukaryotes.[6–8] However, the organism most closely resembles lower eukaryotes in structure. The life cycle of *E. histolytica* consists of an infectious cyst and an invasive trophozoite (Fig. 263.1). The infectious cyst is 10 to 16 μm in diameter, contains four nuclei, and is surrounded by a refractile wall (Fig. 263.2A). Trophozoites are 10 to 60 μm in diameter and have one nucleus with a central karyosome or endosome (Fig. 263.2B). The quadrinucleate cyst is highly resilient and can survive in the environment for weeks to months. *E. histolytica* infection occurs when cysts are ingested in contaminated food or water. Excystation occurs in the small or large bowel, giving rise to eight daughter trophozoites. Trophozoites can colonize or invade the large bowel, but cysts are never found in tissue. About 10% of colonized individuals develop invasive disease characterized by flask-shaped colonic ulcers due to disruption of the intestinal mucosal barrier by the trophozoite. Trophozoites can also enter the bloodstream through the portal venous system and spread to other organs. Interaction of the amebic strain with bacterial flora as well as host factors (malnutrition, diet, sex, age, immune status) may influence whether infection results in colonization or invasive disease. Trophozoites reproduce by binary fission and encyst within the colon, excrete cysts into the environment in the stool, and thus perpetuate the life cycle.

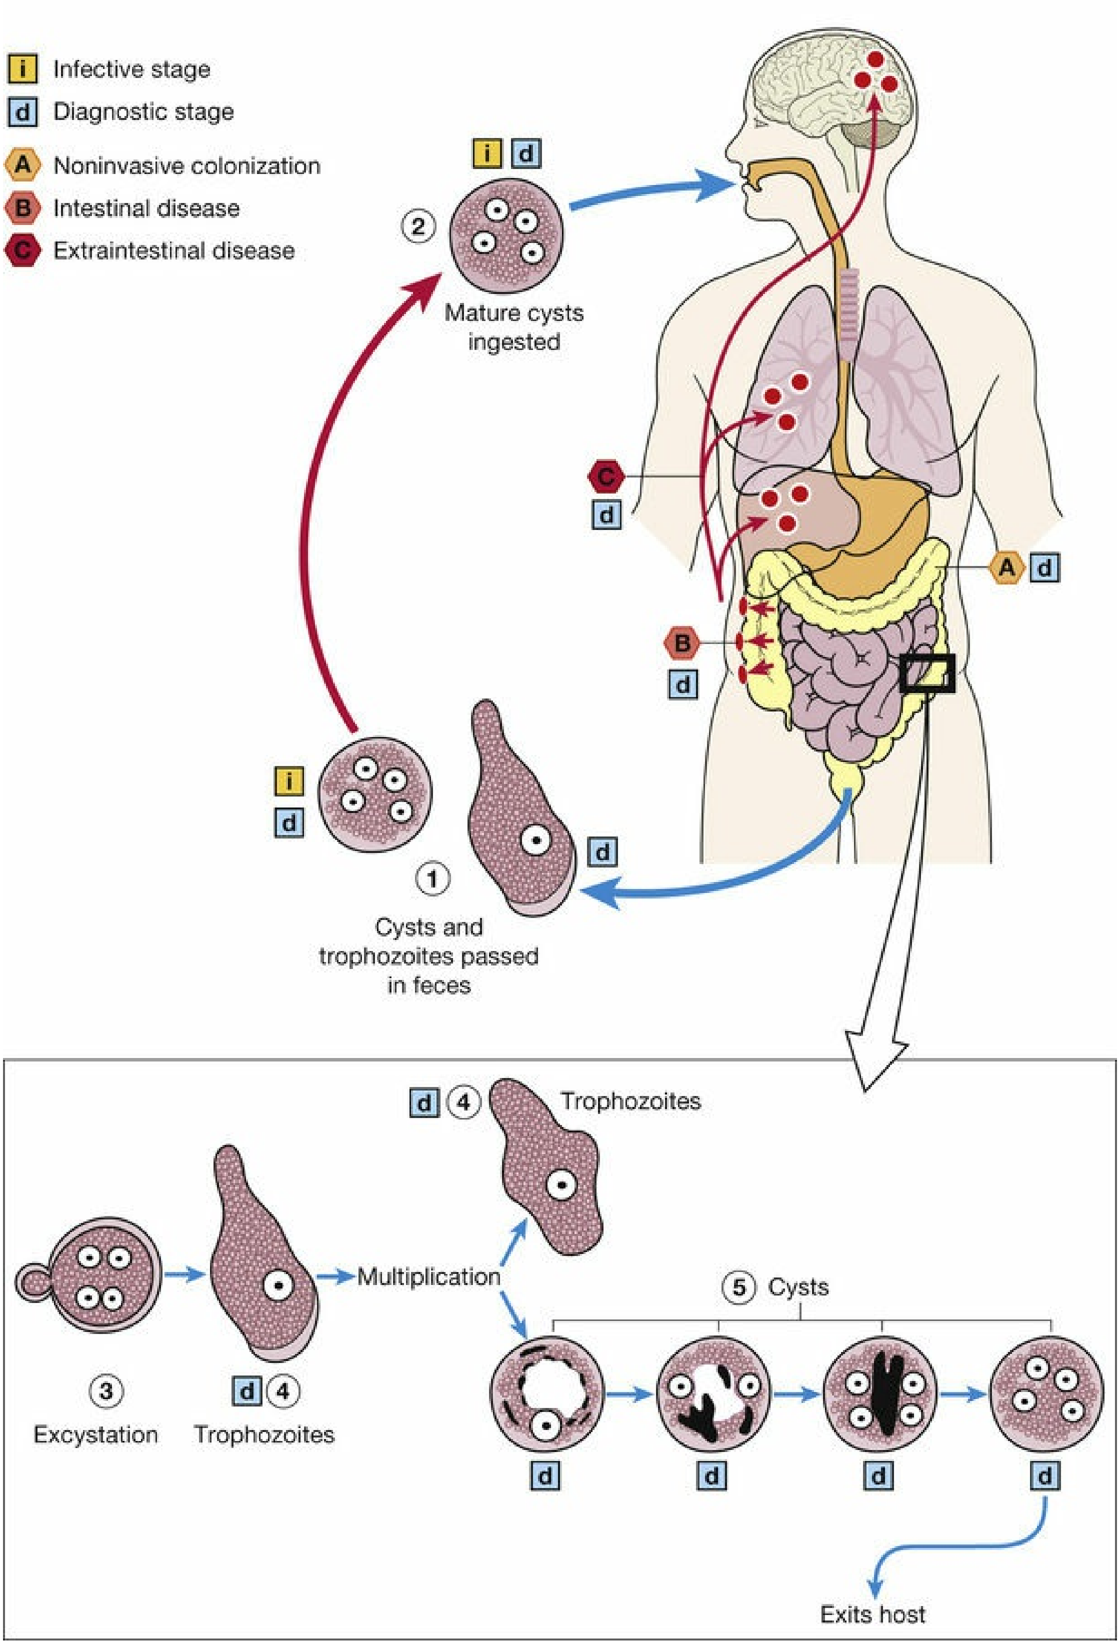

FIGURE 263.1 Life cycle of *Entamoeba histolytica*. Cysts and trophozoites are passed in feces (*1*). Cysts are typically found in formed stool, whereas trophozoites are typically found in diarrheal stool. Infection by *E. histolytica* occurs by ingestion of mature cysts (*2*) in fecally contaminated food, water, or hands.

Excystation (*3*) occurs in the small intestine, and trophozoites (*4*) are released, which migrate to the large intestine. The trophozoites multiply by binary fission and produce cysts (*5*), and both stages are passed in the feces. Because of the protection conferred by their walls, the cysts can survive days to weeks in the external environment and are responsible for transmission. Trophozoites passed in the stool are rapidly destroyed when outside the body, and if ingested would not survive exposure to the gastric environment. In many cases, the trophozoites remain confined to the intestinal lumen (*A:* noninvasive infection) of individuals who are asymptomatic carriers, passing cysts in their stool. In some patients the trophozoites invade the intestinal mucosa (*B:* intestinal disease), or, through the bloodstream, extraintestinal sites such as the liver, brain, and lungs (*C:* extraintestinal disease), with resultant pathologic manifestations. It has been established that the invasive and noninvasive forms represent two separate species, respectively *E. histolytica* and *E. dispar*. These two species are morphologically indistinguishable unless *E. histolytica* is observed with ingested red blood cells (erythrophagocystosis). Transmission can also occur through exposure to fecal matter during sexual contact (in which case not only cysts, but also trophozoites could prove infective). Pathogenesis

A well-defined sequence of events occurs during amebic invasion of the colonic mucosa.[9–11] First, trophozoites adhere to colonic mucins and epithelial cells through interaction of an amebic galactose/*N*-acetyl-D-galactosamine (Gal/GalNAc) inhibitable adherence lectin to host glycoconjugates.[12,13] Then, secreted proteolytic enzymes disrupt the intestinal barrier and facilitate tissue penetration by trophozoites.[14–16] Trophozoites kill host epithelial and immune cells, resulting in tissue destruction. This process was described as a three-part process in vitro that includes adherence, cytolysis, and phagocytosis. Target cell killing is contact dependent and mediated by the amebic Gal/GalNAc inhibitable lectin.[17,18] The heavy subunit of lectin is encoded by a multigene family, is highly expressed in trophozoites, and is highly conserved in *E. histolytica* isolates worldwide, thus having important implications for vaccine development.[19,20] Lectin also mediates serum resistance by inhibiting assembly of the membrane attack complex of human complement on the surface of the ameba.[21]

The mechanism of cytolysis has been the subject of intense investigation. In lymphocytes killed in vitro by *E. histolytica*, compaction of nuclear chromatin, cytoplasmic condensation, and membrane blebbing occur, suggesting an apoptotic mechanism of cell killing.[22] Furthermore, activation of host cell caspases occurs within minutes of contact by trophozoites, and caspase 3 activation specifically by *E. histolytica* leads to activation of apoptosis.[23] Amebapore is a 5-kd polypeptide with pore-forming activity that may be a major effector molecule in mediating cytolytic activity but does so by mechanisms other than inducing apoptosis.[24,25] Amebapore may coact with other virulence factors, perhaps by facilitating entry of amebic proteases into host cells analogous to perforin/granzyme-mediated cell killing by cytotoxic T lymphocytes. Finally, within seconds of contact by an amebic trophozoite, the target cell's cytoplasmic calcium level rises about 20-fold, and cell death occurs in 5 to 15 minutes.[26] On incubation of Chinese hamster ovary cells with purified amebic Gal/GalNAc lectin, a nonlethal, reversible rise in intracellular calcium concentration occurs, suggesting that amebic adherence lectin may be cytotoxic directly.[26,27] Recently, the three-part process of adherence, cytolysis, and phagocytosis has been called into question. It has been demonstrated that *E. histolytica* ingests distinct pieces of living human cells, resulting in intracellular calcium elevation and eventual cell death. This process is called trogocytosis (from the Greek *trogo,* which means “to nibble”).[28]

Immunity

Innate Immunity.

Amebas encounter natural barriers in the intestine and systemic circulation after extraintestinal invasion. In the gut, innate barriers prevent potential pathogens and antigens from gaining access to the underlying epithelium, a process called *nonimmune exclusion*. Gastrointestinal tract mucins are the first line of host defense against *E. histolytica*. Binding sites of mucins have been shown to compete with binding sites of underlying epithelium, preventing attachment of pathogens to the intestinal wall.[29]

The nutritional hormone leptin has been shown to have an important role in neutrophil recruitment. Children with mutation in the leptin receptor (Q223R) were found to have increased susceptibility to amebiasis.[30] Similarly, mice with the 223R mutation had delayed clearance of ameba from bowel and diminished neutrophil recruitment to the site of infection. This suggests that leptin plays an important role in neutrophil chemotaxis.[31]

The human complement system is an important early host defense against bloodstream dissemination of *E. histolytica.* The major *E. histolytica* extracellular proteinase, a 56-kd neutral cysteine proteinase, activates complement in the fluid phase.[32]

Acquired Immunity.

Tissue invasion results in rapid development of acquired immune responses. In a prospective cohort study in Bangladesh, children with immunoglobulin A (IgA) anti-Gal/GalNAc lectin in stool on enrollment developed 64% fewer *E. histolytica* infections during the first 5 months of follow-up compared with antibody-negative children.[33] Apart from serum and secretory IgA, the dominant class of antibodies produced against *E. histolytica* appears to be IgG.[34]

In one study, higher median interferon γ (IFNγ) levels in children was associated with >50% reduction in risk for *E. histolytica* diarrhea and longer survival without *E. histolytica* diarrhea.[35] IFNγ production was lower in malnourished children, which has been associated with *E. histolytica* infections. Innate and acquired IFNγ responses were not distinguished.[35]

Epidemiology

The greatest morbidity and mortality due to *E. histolytica* occurs in developing nations, where sanitary conditions are poor, particularly in the Indian subcontinent, Africa, and Central and South America.[36] Disease is more severe in elderly, young, or malnourished individuals, individuals on immunosuppression, and pregnant women. Reports have documented the bidirectional relationship between malnutrition and morbidity associated with diarrhea.[37–45] Intestinal amebiasis occurs equally in males and females; however, 90% of amebic liver abscesses in adults (but not children) occur in males.[46–48] Recently, a molecular mechanism to explain this discrepancy was found. In a mouse model, testosterone levels were found to influence activation of natural killer T cells, with higher testosterone levels resulting in lower IFNγ produced from natural killer T cells and thus larger liver abscesses.[49]

E. histolytica and *E. dispar* infect about 500 million people worldwide. Fortunately, most people previously believed to be infected with *E. histolytica* carry *E. dispar*, which does not cause human disease.[2] With the discovery and new understanding of *E. bangladeshi* and *E. moshkovskii*, there is an expanding spectrum of *Entamoeba* that can be pathogenic in humans. The best estimate is that approximately 40 to 50 million symptomatic *E. histolytica* infections occur worldwide annually.[50] In Hue City, Vietnam, the annual incidence of amebic liver abscess was 21 cases per 100,000.[51]

Studies in Mexico demonstrated 8.4% seroprevalence. Similarly, in Fortaleza, Brazil, high rates of *E. histolytica* antibodies were detected. In Bangladesh, seroprevalence is about 50% by age 5 years.[52] Worldwide, approximately 100,000 deaths occur from amebiasis annually, making it the third leading cause of death from parasitic disease.[53,54]

Most individuals with amebiasis are infected by ingestion of food or water contaminated with feces containing cysts, but other modes of transmission, including oral anal sex and contaminated enema apparatus, have been reported.[55,56] Groups at increased risk in developed nations include immigrants from endemic areas, long-term visitors to endemic areas, people in group homes and institutions for mentally disabled, men who have sex with men (MSM), and people with AIDS.[36,57,58] Over the past few decades, there has been an increase in sexually transmitted *E. histolytica* in Australia and East Asian developed nations such as Japan, Taiwan, and Korea, concurrent with an increase in men who MSM and in people with HIV infection. In Japan, nearly 80% of amebic cases diagnosed are in MSM, and positive serology for *E. histolytica* was seen in 21% of roughly 1300 HIV patients screened.[59–62]

In the United States, amebiasis is the third most common cause of parasitic infections, with combined prevalence of *E. histolytica* and *E. dispar* estimated at 4%.[36,63] High prevalence (40% to 50%) was described in MSM in New York City and San Francisco during the late 1970s, although invasive disease seemed uncommon (likely owing to predominant species *E. dispar*).[64] A retrospective review of more than 34,000 patients with HIV infection in the US from 1990 to 1998 showed a lower incidence of 13.5 cases per 10,000 person-years.[57] Approximately 2900 cases of amebiasis were reported to the Centers for Disease Control and Prevention in 1993 and 1994. In 1993, 33% of patients reported were Hispanic, and 17% were either Asians or Pacific Islanders.[65] Since 1994, amebiasis is no longer a US nationally notifiable disease.

Clinical Manifestations

Noninvasive Intestinal Infection.

Noninvasive intestinal infection with an ameba identified morphologically as *E. histolytica* could be due to nonpathogenic *E. dispar*, although asymptomatic colonization can be seen with *E. histolytica* as well. In noninvasive infection, examination of stool samples typically reveals no occult blood or amebic trophozoites containing ingested red blood cells. In rural Mexico, a study using polymerase chain reaction (PCR) showed that *E. histolytica* caused a higher rate of asymptomatic infection than *E. dispar* (14% vs. 10%), suggesting a predominant distribution of *E. histolytica* strains of low invasive potential in that community.[66] Similarly, a study in Brazil showed that 11% of the population studied was colonized with *E. histolytica*, and 85% of study participants cleared the infection within 45 days without treatment.[67] Of individuals with asymptomatic colonization, 10% can go on to develop invasive disease within 1 year.[68]

Amebic Colitis (Intestinal Amebiasis).

Patients with *E. histolytica* colitis typically have a 1- to 3-week history of worsening diarrhea progressing to grossly bloody dysenteric stools with abdominal pain and discomfort. Children can have rectal bleeding without diarrhea.[69] Illness lasts >4 weeks in about 20% of patients. Constitutional symptoms frequently are mild. Whereas fever is present in only one third of patients, weight loss is common. Fecal leukocytes may not be present, but virtually all patients have heme-positive stools (Table 263.1; Fig. 263.3).[70–72] Patients with chronic, nondysenteric intestinal amebiasis may complain for months to years of abdominal pain, flatulence, intermittent diarrhea, mucus in stools, and weight loss. One third of patients with amebic colitis in central Virginia reported symptoms for >1 year. Amebic colitis can be confused with inflammatory bowel disease (IBD) in children, potentially leading to a fulminant course if amebic colitis is treated mistakenly with corticosteroid therapy. Amebic colitis also can also exacerbate IBD. A high index of suspicion should be maintained in children from endemic regions, travelers, and those with compromised immune systems.[73] The differential diagnosis in patients with bloody diarrhea include infectious causes *(Entamoeba, Shigella, Salmonella,* and *Campylobacter* spp., *Clostridium difficile,* enteroinvasive and enterohemorrhagic *Escherichia coli,* and *Balantidium coli)* and noninfectious diseases (IBD and gastrointestinal tract bleeding due to diverticulitis). Often the diagnosis of amebic colitis is difficult because manifestations can be insidious or chronic, bleeding can occur without diarrhea, fever is an unusual finding, a single stool examination for parasites is insensitive, histopathologic confirmation of infection in biopsy specimens can be difficult, and serologic tests have limited utility in the acute setting.

Acute Fulminant or Necrotizing Colitis.

Fulminant or necrotizing amebic colitis (see Fig. 263.3) is an unusual (about 0.5% of cases) and severe complication of amebic colitis occurring more frequently in patients inappropriately treated with corticosteroid therapy; surgical intervention usually is required, and mortality exceeds 40%.[74,75] With full colonic involvement, mortality rates may be >90% in children and adults.[76] Abdominal pain, distention, and rebound tenderness are present in most patients with fulminant colitis, although frank guarding is uncommon. Indications for surgery include failure to respond to antiamebic therapy (e.g., localized abscess formation from perforation or persistence of abdominal distention and tenderness despite therapy) and toxic megacolon. Early diagnosis and surgical intervention is associated with improved prognosis. Poor prognostic indicators include prolonged duration of symptoms, invasion of trophozoites into the bowel wall, and a low peripheral white blood cell count.[76] Partial colectomy with colostomy is recommended over primary anastomosis for localized colonic disease as the friable bowel wall predisposes to incompetent anastomoses. For extensive disease, total colectomy has achieved better results.[74,75]

Ameboma.

Ameboma, a segmented mass of granulation tissue in the cecum or ascending colon, represents the hyperplastic granuloma related to amebic abscess in the bowel wall. Ameboma occurs in 0.5% to 1.5% of adults and children with intestinal amebiasis. Presentation usually is with a tender, palpable, abdominal mass. At diagnosis, amebic dysentery is present concurrently in two thirds of patients. An ameboma typically appears as single or multiple "apple core" lesions on a barium enema study, with irregular margins and distortion of the folds; the diagnosis is established with colonoscopy and biopsy. Lesions usually resolve with antiamebic therapy and do not require surgery.[70–72] In a case report of surgery performed for intussusception with a lead mass expected to be a lymphoma, an ameboma was found.[73]

Intestinal stricture occurs in the colon in <1% of patients with amebic dysentery; *E. histolytica* can be identified in the granulation tissue. Strictures usually respond to antiamebic therapy without surgical intervention.

Liver Abscess.

Amebic liver abscess (ALA) is considered one of the most common extraintestinal manifestations of amebiasis; 5% occur in children.

Even in endemic regions, ALA in neonates and in infants younger than 1 year is exceptionally rare. Adults and young children typically have fever, abdominal pain, and tender hepatomegaly; neonates tend to have fulminant onset of symptoms that mimic sepsis.[49,77] Infants with ALA are more likely than adults to have colitis concurrently despite negative stool examinations for ova and parasites.[49] In adults (but not in children), ALA occurs predominantly in males and can manifest as an acute or chronic illness. In one study, 85% of patients who had symptoms for <10 days had fever and abdominal pain. Chronic illness (2−12 weeks of symptoms) is more common and manifests with hepatomegaly and weight loss. Hepatic tenderness is common, but peritoneal signs and jaundice are unusual. Eighty percent of abscesses are singular and found in right lobe of liver, and thus pain is typically in right upper quadrant, although it can be located in the epigastric region or left upper quadrant, or referred to the right shoulder. Atelectasis, elevation of the right hemidiaphragm, and serous pleural effusion occur in 75% of patients with ALA and alone do not represent primary thoracic disease (Table 263.2).[47–49,71,78–82]

TABLE 263.2

Characteristic	Percentage of Patients Affected
Symptoms >4 wk	21–51
Fever	85–90
Weight loss	33–50
Diarrhea	20–33

Jaundice	6–10
Abdominal tenderness	84–90
Hepatomegaly	30–50

Pleuropulmonary amebiasis is the most common complication of ALA and occurs in up to 35% of patients. Other, less common extraintestinal manifestations include empyema and pericardial effusions resulting from direct extension from a hepatic abscess and producing fluid that is often described as looking like anchovy paste on thoracentesis. Amebic abscess of the brain usually is detected at autopsy. Cutaneous amebiasis has been described perianally from an enterocutaneous fistula or as an amebic ulceration of the penis or cervix. Genitourinary amebiasis and splenic abscesses also can occur secondary to hematogenous spread of amebic trophozoites.[71,78,83,84]

Growth and Cognitive Complications.

Diarrheal illness significantly influences morbidity of children in developing nations. Among 298 Bangladeshi children aged 2 to 5 years observed prospectively for 8.2 years, *E. histolytica* infection occurred at least once in 90%, and repeat infection occurred in 68%. *E. histolytica* infection had a significant effect on growth, and stunting was more frequent with *E. histolytica* infection compared with cryptosporidia, enterotoxigenic *E. coli*, and *Giardia*-associated diarrheal illness. Moreover, the relative risk for diarrheal illness also was higher in malnourished children.[85,86] Children with *E. histolytica* dysentery, compared with other etiologies, had lower Wechsler Abbreviated Scale of Intelligence scores after adjusting for environmental factors.[87]

Laboratory Findings and Diagnosis

Microscopy-based methods are not capable of differentiating pathogenic *E. histolytica* from *E. dispar* and *E. moshkovskii;* therefore microscopy should not be used solely to make the diagnosis of amebiasis. The possible exception is visualization of trophozoites containing ingested red blood cells, which does favor *E. histolytica* infection over *E. dispar* colonization.[88–90]

Among several antigen detection assays for diagnosis of human amebiasis, a commercially available enzyme immunoassay (EIA) (TechLab *E. histolytica* II test, TechLab, Blacksburg, VA) is the best available test for specific diagnosis in clinical settings. By detecting the Gal/GalNAc adherence lectin of *E. histolytica* on stool sample specimen, it can distinguish *E. histolytica* from *E. dispar* and *E. moshkovskii*. The sensitivity and specificity of this assay on stool in dysentery disease is >96%.[91] Rapid point-of-care antigen tests are also available for use in developing nations with similar sensitivity and specificity. One such assay, the *E. histolytica* Quik Chek assay (TechLab), was found to have a sensitivity of 98% and specificity of

100% when studied in populations in South Africa and Bangladesh.[92]

Colonoscopy can aid in diagnosis and remains important to evaluate other potential causes of disease. Of note, cathartic or enema preparation of the patient can interfere with visualization of trophozoites. The colonic mucosa appears hemorrhagic in patients with amebic colitis, with discrete, shallow ulcers with raised edges. Wet preparations aspirated or scraped from the ulcer base should be examined for trophozoites. Biopsy should be confined to the ulcer margins; special stains, such as periodic acid–Schiff stain, facilitate identification of *E. histolytica*.[93–95]

Serologic tests for antiamebic antibodies are an important adjunct to diagnosis. These tests can be falsely negative early in the course of disease but generally become positive within 7 to 10 days of illness.[46] More than 90% of patients develop antibodies to *E. histolytica,* which can be detected by indirect hemagglutination (IHA), EIA, counter-immunoelectrophoresis, or agar gel diffusion. IHA is positive in 88% of patients with amebic dysentery, in 70% to 80% of patients with ALA, and in only 5% of the general population in developed nations. Because antibody persists for years after infection, presence cannot be used to distinguish current from prior infection. In endemic areas, 5% to 30% of the population may have antibodies by IHA; thus serology is not as helpful for diagnosis in this population.[96] An EIA for *E. histolytica* galactose inhibitable lectin antigen and salivary IgG antibodies to a recombinant cysteine-rich lectin-derived protein (LC3) is more sensitive and specific for acute amebic colitis compared with EIA for serum anti-LC3 IgG antibodies.[97] Other serologic methods, including dot-EIA and rapid dipstick assay, have been used for diagnosis of different forms of human disease and also can be used for the diagnosis of amebiasis.[98]

Molecular methods have been used to diagnose human amebiasis and to differentiate pathogenic *E. histolytica* from *E. dispar, E. moshkovskii,* and newly discovered *E. bangladeshi.* In stool samples, PCR is more sensitive than the best currently available EIA kit for detection of *E. histolytica* antigens.[99] PCR testing for short tandem of transfer RNA–linked gene repeats also can separate genotypes and has been used for virulence and epidemiologic studies.[100] Real-time PCR assay has been used to diagnose intestinal infection and liver abscess in Bangladeshi patients.[101] The sensitivity of real-time PCR was higher than both traditional PCR and the antigen detection test.

Diagnosis of ALA is made by imaging findings plus serologic testing as stool tests and abscess aspirate frequently are unrevealing.[102] *E. histolytica* antibody can be detected in serum with IHA assay in 70% to 80% of cases, and, before treatment, the TechLab *E. histolytica* II EIA can detect amebic antigen in serum of approximately 96% of patients with ALA.[91] Ultrasonography, computed tomography, and magnetic resonance imaging studies of the liver are equally sensitive for detecting ALA (Fig. 263.4). However, none differentiates amebic from pyogenic abscess.[103–106] Six months after therapy, resolution of liver lesions by ultrasonography occurs only in one third to two thirds of cases, and thus follow-up studies are not helpful in evaluating response to treatment.

Treatment

Asymptomatic infection with *E. histolytica* should be treated with an intestinal luminal agent alone because of concern for progression to active disease as well as public health consequence (Box 263.1).

Drugs effective against luminal infection are paromomycin, iodoquinol, and diloxanide furoate (which is not readily available in the US).[107–109] Metronidazole should not be used as sole therapy to treat asymptomatic people because this drug often fails to eradicate organisms from the lumen.

Treat with a luminal agent:

Paromomycin	25–35 mg/kg/day by mouth in 3 divided doses for 7 days
Diloxanide furoate	20 mg/kg/day by mouth (maximum, 1.5 g) in 3 divided doses for 10 days
Iodoquinol	30–40 mg/kg/day (maximum, 2 g) by mouth in 3 divided doses for 20 days

Amebic Colitis/Amebic Liver Abscess

Treat with one of the following *plus* a luminal agent:

Metronidazole	35–50 mg/kg/day (maximum, 750 mg) by mouth in 3 divided doses for 10 days
Tinidazole (≥3 years old)	50 mg/kg/day (maximum, 2 g) by mouth once daily for 5 days

Invasive amebiasis should be treated with metronidazole or tinidazole, plus a luminal agent. Metronidazole does not cure intestinal infection in up to 50% of patients with invasive amebiasis unless therapy is given for a minimum of 10 days. Shorter courses of metronidazole therapy are associated with relapse of invasive infection months later.[110,111] Tinidazole appears to be as effective as metronidazole and better tolerated.[112] If children cannot tolerate pills, the pill can be crushed and made into a suspension.[113] Auranofin, an oral gold-containing compound used to treat rheumatoid arthritis in adults, was shown to have activity against *E. histolytica* in vitro and in vivo. It is currently in clinical trials for treatment of amebiasis in adults.[114] After treatment is complete, repeated stool EIA studies should be performed to document eradication.

Fever from ALA is expected to be reduced after 3 to 4 days of treatment with metronidazole. Chloroquine, dehydroemetine, and percutaneous drainage of the liver abscess each has been used successfully in addition to metronidazole for the unusual case not responding to metronidazole alone.[109–111,115,116] Percutaneous drainage is not required for most ALAs and does not speed recovery.[115] Definitive indications for ALA aspiration are controversial, but in general consideration should be given in patients where diagnosis is uncertain (if concern for pyogenic abscess or superinfection), those who have failed to respond to metronidazole therapy after 4 days of treatment, individuals with large left lobe abscesses (because of risk for rupture into pericardium), and severely ill patients when rupture seems imminent.[55]

Prevention

Prevention of *E. histolytica* requires disruption of the fecal-oral spread of amebic cysts. People should be advised of the risk associated with traveling to endemic areas, safeguards to prevent ingesting colonic organisms, and the risk involved in sexual practices that include oral-anal contact. Because humans and primates are the only known reservoirs of *E. histolytica,* a successful vaccine potentially could eliminate amebiasis.[2,117]

Key Points

Epidemiology, Clinical Features, and Diagnosis of *Entamoeba histolytica* Infection

Microbiology and Histopathology

- Pseudopod-forming, nonflagellated protozoan parasite
- Life cycle involves a quadrinucleate cyst and invasive trophozoite.
- Flask-shaped colonic ulcers can be found in invasive disease.

Epidemiology

- Approximately 40 to 50 million symptomatic infections and up to 100,000 deaths occur annually worldwide.

- Amebiasis is the third most common cause of parasitic death worldwide.

- Increased risk for severity in elderly, young, or malnourished individuals, immunosuppressed patients, and pregnant women

- *Entamoeba moshkovskii* and *Entamoeba bangladeshi,* which appear morphologically similar to *Entamoeba histolytica,* also can cause symptomatic disease with diarrhea.

Clinical Features

- Asymptomatic colonization

- Intestinal amebiasis and associated complications

- Amebic colitis

- Acute fulminant or necrotizing colitis

- Ameboma

- Liver abscess

- Growth and cognitive complications

- Other uncommon manifestations include pleuropulmonary disease, empyema and pericardial effusions, amebic brain abscess, and cutaneous amebiasis.

Diagnosis

- Microscopic identification of the parasite in stool, liver abscess, or biopsy is not sensitive.

- Stool antigen detection is highly sensitive and specific (>96%).

- Real-time polymerase chain reaction assay is a highly sensitive, research-based test for the diagnosis of intestinal and liver infections.

- Serum antibody testing before the institution of treatment can detect infection in 70% to 96% depending on assay used.

- Colonoscopy is an important tool to evaluate for other diseases. Wet preparation of material from the ulcer base and special stains such as periodic acid–Schiff stain should be performed for diagnosis.

- Imaging with ultrasound, computed tomography, and magnetic resonance imaging cannot differentiate pyogenic from amebic abscesses and are equally sensitive for detecting amebic liver abscess.

Treatment

- Amebic colitis or amebic liver abscesses should be treated with metronidazole or tinidazole plus a luminal agent.

Other *Entamoeba*, Amebas, and Intestinal Flagellates

Joanna Nelson, Upinder Singh

In addition to *Entamoeba histolytica*, other pseudopod-forming nonflagellated protozoan parasites that infect the human intestinal tract include *E. dispar, E. hartmanni, E. polecki, E. chattoni, E. coli, E. moshkovskii, E. gingivalis,* and *E. bangladeshi. E. invadens* does not infect humans but is of great value as a laboratory model in human research of amebiasis. The highly virulent species *E. histolytica* is distinguished from the other, mostly nonpathogenic, intestinal pseudopod-forming protozoa by morphologic appearances of the cyst and trophozoite forms or by differences in antigens or DNA sequences (see Chapter 263).

Entamoeba dispar

E. dispar is a nonpathogenic intestinal commensal protozoan that is indistinguishable morphologically from *E. histolytica* on light microscopy. About 90% of the infections previously attributed to *E. histolytica* actually were due to *E. dispar*. Symptomatic *E. dispar* infection has not been demonstrated in humans.[1] The prevalence of amebic intestinal colonization in some male homosexual populations is as high as 33%, and *E. dispar* commonly is found in stool specimens from patients with acquired immunodeficiency syndrome.[2] A stool antigen detection test that differentiates nonpathogenic *E. dispar* from pathogenic *E. histolytica* is available commercially (TechLab E. histolytica II test, TechLab, Blacksburg, VA).[3]

Entamoeba moshkovskii

E. moshkovskii is morphologically identical to *E. histolytica;* however, improved diagnostic techniques have allowed for its identification in human specimens.[4] Although earlier studies of *E. moshkovskii* failed to show an association with clinical illness, studies from Asia and Australia suggest a potential role in symptomatic gastrointestinal tract illness and disease in a mouse model of colitis.[5–8] Future studies will be important in defining the pathogenic potential of this *Entamoeba* spp.

Entamoeba bangladeshi

E. bangladeshi is morphologically identical to *E. histolytica.* It was first described when polymerase chain reaction testing was performed on both diarrheal and surveillance samples from patients in Bangladesh and a novel sequence was discovered.[9] Further investigation is required to determine the clinical significance of *E. bangladeshi.*

Entamoeba polecki

E. polecki is a common parasite of pigs, wild boars, and monkeys in the tropics and subtropics.[10] Humans acquire infections accidentally, and whether this organism can produce disease in humans is unknown. In Papua New Guinea, where pigs are the main domestic animals, up to 30% of people can be colonized.[11] The trophozoite stage of *E. polecki* has a frothy cytoplasm and resembles that of *E. histolytica;* the cyst, however, contains a single nucleus and may contain inclusion bodies and abundant fragmented chromatoidal bars. *E. polecki* has been treated successfully with metronidazole, ornidazole, and furamide, with metronidazole given in a regimen similar to that used for *E. histolytica* infection.[12]

Entamoeba chattoni

E. chattoni is a parasite of nonhuman primates, although accidental human infections have been reported on rare occasions, mainly related to contact with monkeys.[13] There is no evidence that this species produces clinical disease in humans; however, its uninucleated cysts have been confused with cysts of *E. histolytica*.[14]

Entamoeba invadens

E. invadens is a pathogenic species in snakes, producing symptoms similar to human amebiasis.[15] *E. invadens* is not important medically but has been used extensively as a laboratory model in the study of *E. histolytica* encystation.[16,17]

Entamoeba gingivalis

E. gingivalis is found in the mouth and is associated with poor dental hygiene.[18] In patients infected with human immunodeficiency virus, *E. gingivalis* infection is associated with periodontal disease, although a causal relationship has not been established.[19,20] *E. gingivalis* has no cyst form and can be confused with *E. histolytica* when sputum is examined in patients with suspected pulmonary amebic or pyogenic abscess.[19] On rare occasions, *E. gingivalis* has been recovered from other sites, including neck nodules and the uterus.[21–23] Treatment with metronidazole has been reported to be effective.[20]

Entamoeba hartmanni

E. hartmanni is a nonpathogenic organism also found in the colon. This organism is identical morphologically to *E. histolytica*, except for its smaller size (trophozoites <12 μm and cysts <10 μm in diameter).[19]

Entamoeba coli

E. coli is nonpathogenic and the most prevalent human ameba. This organism can be distinguished from *E. histolytica* because of the larger cyst (>15 µm in diameter), the presence of 5 to 8 nuclei, and an eccentric karyosome. The presence of this organism in stool is not an indication for treatment but is a useful indicator of fecal-oral exposure.[19]

Dientamoeba fragilis

D. fragilis trophozoites are binucleated and variable in size (5 to 12 µm in diameter). The prevalence of *D. fragilis* is 0.4% to 42% worldwide[24] and is up to 50% in groups at high risk for fecal-oral transmission, including children, people in institutional settings, and people in settings with inadequate hygiene.[25] Previously isolated only from animal models, cyst and precystic forms of *D. fragilis* have now been isolated from human stool specimens. Cysts have a distinct wall; they are binucleate with a large central karyosome. Precysts range in size from 4 to 5 µm and contain darkly staining cytoplasm.[26]

The mode of transmission for *D. fragilis* remains unclear. Several studies have shown an association of concurrent pinworm *Enterobius vermicularis* with *D. fragilis* parasitosis; others have not.[25,27–30] Symptoms have been observed in 20% to 58% of people infected with *D. fragilis*[25] and can include abdominal pain, loose stools, nausea, anorexia, vomiting, bloating, flatulence, weight loss, and fever.[24,25] Chronic symptoms have been reported, with up to 32% of patients having persistent diarrhea.[29] There have been reports of associations of *D. fragilis* with irritable bowel syndrome, appendicitis, and marked eosinophilia.[31–33]

The diagnosis of *D. fragilis* is based on microscopic examination of stool. Multiple fresh samples should be examined with a permanent stain such as hematoxylin, trichrome, or celestine blue B. Molecular methods also have been used to identify the parasite directly in stool.[4,34] Treatment is recommended when significant symptoms occur. Iodoquinol, metronidazole, tetracycline, paromomycin, and secnidazole have been effective in eradicating the parasite in the limited number of patients studied.[30,35–38]

However, a recent randomized control trial showed that a course of metronidazole was no better than placebo in improving symptoms.[39]

Chilomastix mesnili

The most prevalent nonpathogenic flagellate, *C. mesnili* can be distinguished from *Giardia intestinalis* on the basis of its lemon-shaped cyst and a single nucleus. Some identical forms have been found in other animals, but it is not clear that these animals have any role in the epidemiology of human infections.[10]

Iodamoeba butschlii

I. bütschlii, a nonpathogenic commensal of the colon, can be distinguished from *E. histolytica* in trophozoite form because of its smaller size and sluggish motility, and in the cyst form because of its characteristic large glycogen vacuole, which stains with iodine on a wet preparation.[19]

Giardia intestinalis (Giardiasis)

Matthew Washam, Robert W. Frenck Jr.

Giardia intestinalis is a flagellated protozoan that infects the duodenum and upper small intestine. *Giardia* is the most commonly identified enteric parasite in the United States and Canada. Infection can be asymptomatic or associated with a variety of intestinal manifestations. Factors contributing to this variation include genotype of the *Giardia* strain, the number of cysts ingested, the age of the host, and the status of the host's immune system. Diagnosis is made by detection of cysts or trophozoites in stool specimens, duodenal fluid, or small bowel biopsy or by detection of *Giardia* antigens in stool specimens. Several drugs are effective in treating people infected with *Giardia*. Prevention occurs by use of appropriate hand hygiene and prevention of ingestion of contaminated food and water, including contaminated recreational water.

Pathogen and Pathogenesis

Giardia, an intestinal flagellate in the division Protozoa, is distributed globally and has been detected in nearly all classes of vertebrates, including domestic animals and wildlife. Six *Giardia* species are currently recognized, and *Giardia intestinalis* (also known as *Giardia duodenalis* and *Giardia lamblia*) is the only species found in humans.[1] Molecular typing of *G. intestinalis* strains reveal that human strains are placed in two of eight specialized genetic groups referred to as *assemblages* (A to H), which are species specific.[1–5] Assemblages A and B infect primarily humans and primates, although other mammalian hosts can be infected as well. Assemblages C through H do not appear to infect humans. These findings suggest that *G. intestinalis* does not have as high a level of potential transmission as a zoonotic disease as thought previously.[4–7]

Giardia has two major stages in its life cycle: the trophozoite is the replicative stage within the host, and the cyst is the relatively inert infectious stage allowing for prolonged survival to a variety of environmental stimuli.[8,9] After ingestion, excystation of *Giardia* cysts occurs in the proximal small intestine, releasing trophozoites that undergo repeated mitotic division and form environmentally resistant cysts in response to bile salts and other conditions.[10] Trophozoites are 10 to 20 μm in length and 5 to 15 μm in width, with a convex dorsal surface, two nuclei, four symmetrically placed flagella originating at the anterior pole of the nucleus, and a ventrally located adhesive disk (Fig. 265.1). The disk is composed of microtubules, microribbons, and cross-bridges consisting of proteins referred to as *giardins* and is responsible for attachment to the intestinal epithelium and subsequent colonization.[11] Rotavirus coinfection may act synergistically to enhance pathogenicity by allowing for more successful attachment.[12,13] Trophozoites divide by longitudinal binary fission, with a doubling time of 6 to 12 hours in vitro. *Giardia* undergoes frequent antigenic variations during infection of humans and animals during encystations and during culture in vitro.[14–16]

As detached trophozoites pass through the intestinal tract, they encyst to form smooth, oval-shaped, thin-walled cysts that measure 8 to 12 μm in length and 8 to 10 μm in width and are passed in feces.[1] In patients with watery diarrhea and rapid transit time, trophozoites may be found in stool specimens but are not stable once passed. After ingestion of *G. intestinalis* cysts, an incubation period of 3 to 25 days (median, 7–10 days) ensues before onset of symptoms.

The pathogenesis of diarrhea in giardiasis is thought to be related to several factors, including (1) the number of organisms ingested, (2) the specific infecting strain, (3) nonantibody protective factors in the gastrointestinal tract, and (4) the immune response of the host.[17]

Studies in adults show that ingestion of as few as 10 to 100 fecally derived cysts is sufficient to initiate infection, and studies in children document person-to-person transmission in childcare centers.[18] *Giardia* cysts are infectious immediately on being excreted in feces and remain viable for 3 months in water at 4°C.[5,19] Freezing decreases infectivity, whereas heating, drying, and seawater appear to eliminate the ability of the organism to infect.[19–21] The exact mechanisms used by *Giardia* to cause diarrhea have not been fully elucidated.[22,23] Morphologic damage to intestinal epithelial cells and their brush borders can occur after colonization, with the degree of mucosal abnormality correlating with severity of diarrhea.[16,24] Varying degrees of villous atrophy have been observed in intestinal biopsy specimens from people with giardiasis, with most having normal or relatively mild villus shortening.[25,26] This microvilli disorganization may explain some of the physiologic changes with giardiasis. Disaccharidase deficiencies, usually of lactase, in the microvillous membrane have been documented in humans and in the mouse model of *G. muris* infection.[27,28] Protein, fat-soluble vitamins, and D-xylose malabsorption also are associated with *Giardia* infection in humans.[29,30] Decreased intestinal absorption of oral antimicrobial agents can occur and lead to treatment failure of other infections.[31] Simultaneous colonization of the small intestine with *Giardia* and Enterobacteriaceae may contribute to malabsorption by deconjugation of bile salts in some patients.[32] Production of enterotoxin has not been demonstrated.

Relatively little is known about protective responses in human giardiasis. Both B and T lymphocytes appear to play a role in protective immunity, as shown by the predisposition to giardiasis in patients with common variable immunodeficiency and in children with X-linked agammaglobulinemia.[10,33–36] Anti-*Giardia* immunoglobulin G (IgG) can be found in >80% of patients during symptomatic infection.[17,37,38] IgG antibody tends to persist, thus limiting usefulness in distinguishing current from past infection in individual patients.[38] An association between the presence of IgG anti-*Giardia* and protective immunity is not clear. Serum IgM antibodies increase early in infection and decrease rapidly after 2 to 3 weeks.[38,39] Serum IgA antibodies can be absent in symptomatic people; measurement has limited diagnostic value. Secretory IgA (sIgA) is presumed to be important in host protection.[17] Human milk is protective against giardiasis in infants; this protection correlates with the amount of specific sIgA anti-*Giardia*.[40–43] Human milk is lethal to *Giardia* trophozoites through action of free fatty acids, which are liberated from milk triglycerides by bile salt −stimulated lipase.[44–46] Long-term CD4 T-lymphocyte−driven cellular immunity may occur variably after *Giardia* infection, with cross-reactivity between assemblages A and B.[47]

Epidemiology

Giardiasis occurs worldwide and is the most commonly identified human intestinal parasite in the US and Canada.[48–53] Giardiasis has been a nationally notifiable gastrointestinal tract illness in the US since 2002. Reporting of giardiasis occurs in 44 states (exclusions are Tennessee, Oklahoma, Kentucky, Mississippi, North Carolina, and Texas).[48,50] Age-specific prevalence rates are highest in children 1 to 9 years of age, followed by people 35 to 49 years of age. Giardiasis incidence rates have remained relatively stable in the US since 2002 at 7.2 to 8.7 cases per 100,000 population, with 19,927 cases reported in 2010 (7.6 cases per 100,000 population).[50,51] There are regional variations in incidence with the Midwest and Northwest reporting the highest rates of giardiasis.[50] Most cases were reported between May and September (Fig. 265.2) and were associated with the summer recreational water season and with camping. Males accounted for approximately 56% of reported cases from 2006 to 2010. Although reporting of giardiasis is required by 44 states, because diarrheal diseases often are underreported, these rates underestimate the disease burden attributable to *Giardia*.

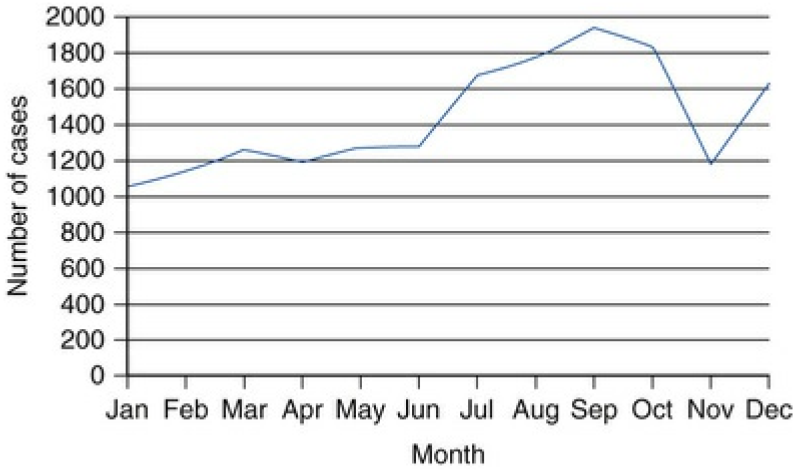

FIGURE 265.2 Number of reported giardiasis cases occurring by month, National Notifiable Disease Surveillance System, United States, 2010 to 2012.[51-53]

Transmission of *G. intestinalis* is more common in certain groups, including (1) children and employees in childcare centers, (2) travelers to disease-endemic areas of the world, (3) close contacts of infected people, (4) people who swallow contaminated drinking water or recreational water, (5) people exposed to infected domestic and wild animals (dogs, cats, cattle, deer, and beaver), (6) people who take part in outdoor activities (e.g., camping or backpacking) who consume unfiltered or untreated water, and (7) men who have sex with men.[48] The relative contribution of person-to-person, animal-to-person, and foodborne and waterborne transmission to sporadic human giardiasis is not well understood.[54–65] Ingestion of surface water treated by faulty or inadequate purification systems has been a commonality of waterborne outbreaks. In addition, drinking untreated mountain stream water is a major risk for hikers. From 2009 to 2010, *Giardia* was identified as the causal agent of 1 (1%) of 81 reported recreational water associated outbreaks and of 5 (11%) of 45 reported drinking water and other nonrecreational water source–associated outbreaks of gastroenteritis in the US.[66,67] Although *Giardia* is one of the most frequently identified parasites associated with waterborne disease outbreaks in the US, foodborne outbreaks of giardiasis are reported rarely.[56,59,63,68,69] During 1998 to 2010, only 18 (0.2%) of 9020 of foodborne outbreaks with a known etiology were associated with *Giardia*.[70,71] Because the infectious dose in adults is only 10 to 100 cysts,[18] person-to-person spread also occurs, particularly in areas of low hygienic standards, crowding, and frequent fecal-oral contact. Person-to-person spread occurs frequently in childcare centers and in families of children with diarrhea.[72–74] As with other enteropathogens, individual susceptibility, lack of toilet training, crowding, and fecal contamination of the environment all contribute to transmission of *Giardia* in childcare centers.[74]

Clinical Manifestations

After excystation and colonization, a broad spectrum of clinical manifestations can occur: (1) asymptomatic excretion of organisms, (2) acute infectious diarrhea, or (3) chronic diarrhea with failure to thrive or persistent gastrointestinal tract symptoms (Table 265.1). Symptoms vary by age, with symptomatic infections more frequent in children than in adults.[75,76] Short-lasting, acute diarrheal disease with or without low-grade fever, nausea, and anorexia is usual; an intermittent or more protracted course occurs occasionally and is characterized by diarrhea, abdominal cramps, bloating, malaise, flatulence, nausea, anorexia, and weight loss.[45,54,75,76] Stools can be profuse and watery initially and later become greasy, foul smelling, and buoyant. Blood, mucus, and fecal leukocytes are absent. Varying degrees of malabsorption can occur, and abnormal stool patterns can alternate with periods of constipation and normal bowel movements. Giardiasis should be considered in any patient with a history of contact with an index case or a young child who attends a childcare center, has traveled recently to an endemic area, or has gastrointestinal tract symptoms, including persistent or intermittent diarrhea and constipation, malabsorption, crampy abdominal pain, abdominal bloating, unexplained gastrointestinal tract symptoms, failure to thrive, or weight loss. Extraintestinal involvement is unusual, but trophozoites occasionally migrate into bile or pancreatic ducts. Infrequently associated conditions with giardiasis include reactive arthritis, urticaria, and retinal changes.[77–80]

The asymptomatic carrier rate of *G. intestinalis* is estimated to be 3% to 7% in the US and as high as 20% in southern regions. In prevalence studies of children younger than 36 months enrolled in childcare centers, *Giardia* cysts have been found in 21% and 26% of asymptomatic children.[81,82] Longitudinal studies have shown that asymptomatic infections are well tolerated.[81,83] Thus neither testing of case contacts nor treatment of asymptomatically infected people is indicated routinely.

Humoral immunodeficiencies, including common variable hypogammaglobulinemia and X-linked agammaglobulinemia, predispose humans to chronic symptomatic giardiasis.[10,34–36] People with sIgA deficiency appear to have an increased risk for *Giardia* infection.[84,85] Children with severe T-lymphocyte deficiencies from thymic dysplasia (DiGeorge syndrome) and patients with acquired immunodeficiency syndrome with a low $CD4^+$ T-lymphocyte count do not have persistent or severe diarrheal episodes from *Giardia.*[17] People with cystic fibrosis have a higher incidence of *Giardia* infection, probably as a result of local factors such as an increased amount of mucus, which may protect the organism in the duodenum.[86]

Diagnosis

A definitive diagnosis is established by detection of *Giardia* trophozoites or cysts in stool specimens, duodenal fluid, or small bowel tissue by microscopic examination using staining methods such as trichrome or direct fluorescent antibody (DFA) assays; by detecting soluble stool antigens using enzyme immunoassays (EIA); or by using molecular techniques including polymerase chain reaction (PCR).[87–90] The traditional method used was identification of trophozoites and cysts on direct smears or concentrated specimens of stool. Identification of *Giardia* in the stool can be difficult because of intermittent excretion of cysts and three stool samples collected on separate days increases sensitivity.[91] Trophozoites are fragile and are more likely to be present in unformed stool as a result of rapid intestinal transit time. Medications, including antimicrobial agents, antacids, antidiarrheal compounds, and certain enema and laxative preparations, can interfere with identification of *Giardia* by altering morphology or by causing a temporary disappearance of parasites from stool specimens. Such compounds should be withheld for 48 to 72 hours before collection of stool for identification of *Giardia.* Contrast material, such as barium used for imaging studies, also masks the presence of parasites, and stools should be examined before performing tests with these materials.

Giardia detection is improved through use of antigen testing and molecular techniques. Antigens shared by trophozoites and cysts excreted in stool specimens include the 65-kd antigen used in commercial diagnostic assays.[87,88,92,93] DFA testing is a sensitive and specific method and is considered the gold standard by many laboratories.[94–102] Commercially available rapid immunochromatogenic cartridge assays and EIAs are alternative antigen-based tests that have variable sensitivity and that can be performed rapidly in laboratories without access to fluorescent microscopy.[91] Molecular testing with PCR offers improved sensitivity over microscopy and can be used for genotype differentiation.[90]

When giardiasis is suspected and stool specimens are negative, the string test, duodenal aspiration, or biopsy can be performed.[96] In a fresh specimen, trophozoites usually can be visualized on direct wet mount. Duodenal biopsy is the optimal method for diagnosis. The biopsy sample can be used to make touch preparations for identifying *Giardia* in tissue sections and for histologic examination, and to identify abnormalities not associated with *Giardia*. Small intestinal biopsy should be considered in patients with characteristic clinical symptoms, negative stool and duodenal fluid specimens, and one of the following: abnormal radiographic findings (such as edema and segmentation in the small intestine), abnormal lactose tolerance test, absent sIgA, hypogammaglobulinemia, or achlorhydria.

Specific antibodies to *Giardia* have been detected and quantified by immunodiffusion, hemagglutination, immunofluorescence, and EIA. Although not typically used in routine diagnosis, serology may serve as a useful indicator of levels of infection within a community.[103] Radiographic studies of the small intestine can show nonspecific findings such as irregular thickening of mucosal folds. The peripheral blood leukocyte count usually is normal; giardiasis is not associated with eosinophilia.

Treatment

Children with acute or chronic diarrhea with failure to thrive, malabsorption, or other gastrointestinal tract symptoms should be treated with an antiprotozoal agent if *Giardia* is identified in stool or a duodenal specimen. Several drugs are available in the US for treatment of giardiasis (Table 265.2).[104–113] Tinidazole, nitazoxanide, and metronidazole are the drugs of choice.[105] Tinidazole and metronidazole are members of the nitroimidazole family. Tinidazole, which is used as single-dose therapy, was approved by the US Food and Drug Administration (FDA) in 2004 for adults and children 3 years and older for treatment of giardiasis.[106–110] Nitazoxanide was approved by FDA in 2003 for use in children with giardiasis and cryptosporidiosis, and more recently for giardiasis treatment in adults.[104–106,112,113] Quinacrine and furazolidone are not available from any US manufacturer, although the drugs can be obtained from several US compounding pharmacies. Paromomycin, a luminally active aminoglycoside that is not absorbed, is less effective than other agents but can be used for treatment of pregnant women.[108] Albendazole is effective against many helminths, making it useful for treatment when multiple intestinal parasites are identified or suspected.[104,105]

TABLE 265.2

Oral Antimicrobial Therapy for Giardiasis

Antimicrobial Agent[a]	Pediatric Dose	Adult Dose
Albendazole (Albenza)	10 mg/kg once daily for 5 days (max., 400 mg/day)	400 mg once daily for 5 days
Furazolidone (Furoxone)	6 mg/kg/day divided into 3–4 doses for 7 to 10 days	100 mg 4 times a day for 7 to 10 days
Metronidazole (Flagyl)	15 mg/kg/day divided into 3 doses for 5 days	250 mg 3 times a day for 5–7 days
Nitazoxanide (Alinia)	12 through 47 months: 200 mg/day divided into 2 doses with food for 3 days 4 through 11 years: 400 mg/day divided into 2 doses with food for 3 days	500 mg twice daily with food for 3 days
Paromomycin[b]	Not recommended	500 mg 3 times a day for 7 days
Quinacrine[c] **(Atabrine)**	6 mg/kg/day divided into 3 doses for 5 days (max., 300 mg/day)	100 mg 3 times a day for 5 days
Tinidazole (Tindamax)	≥3 years of age, 50 mg/kg as a single dose (max., 2 g) with food	2 g as a single dose with food

[a] For refractory cases, metronidazole and quinacrine for 14 days.

[b] Not absorbed; may be useful for treatment of giardiasis in pregnancy.

[c] Not available commercially but can be compounded (contact Professional Compounding Centers of America 800-331-2498 or www.pccarx.com).

A review of comparative trials on treatment of giardiasis reported that cure rates for patients treated with metronidazole (201 of 219, 92%) were higher than for patients treated with furazolidone (126 of 150, 84%; $P < 0.001$).[114] Approximately 7% of metronidazole-treated patients and 10% of furazolidone-treated patients had side effects that were adverse enough to report. A meta-analysis of 31 publications on treatment of giardiasis also showed that metronidazole administered for more than 3 days appears to achieve a better parasitologic cure than do other long-term treatment regimens.[107] Single-dose tinidazole was as effective as longer-term treatments.[107] The clinical response rate of tinidazole was 85%, compared with 80% for metronidazole. One study of furazolidone, which is available in a pediatric liquid formulation, showed a cure rate of 92% after a 10-day course. Metronidazole can be formulated into liquid preparations by special request. Asymptomatic excreters generally are not treated except in specific instances, such as repeated antibiotic treatment failures (possibly related to decreased antibiotic absorption), outbreak control, and prevention of household transmission by toddlers to pregnant women or people with hypogammaglobulinemia or cystic fibrosis.[32,115]

Symptomatic giardiasis recurs in some immunologically normal people despite appropriate therapy and in cases in which reinfection cannot be documented. The ability to isolate trophozoites axenically in culture permits in vitro susceptibility testing of *Giardia* strains, although testing is not standardized, and study of mechanisms of resistance.[116–120] Variable strain susceptibility, as well as resistance, has been demonstrated. Switch to a drug of a different class or combined therapy may be considered for patients whose infection persists after single-drug therapy (assuming that the medication was taken as prescribed and that reinfection is unlikely).[117,118,121–123] Combination therapy with standard doses of metronidazole and quinacrine given for 3 weeks has been effective when studied in a small number of refractory infections.[122]

Prevention

Prevention of giardiasis involves good hygiene and avoidance of water and food that might be contaminated.[48] Infected people and people at risk especially should adhere to strict hand-hygiene techniques after contact with feces, notably caregivers of diapered infants in childcare centers where diarrhea is common and carrier rates are high. People with diarrhea, especially children in diapers, should avoid all swimming venues until diarrhea subsides. Information about recreational water illnesses and control measures is available at www.cdc.gov/healthyswimming/ and www.cdc.gov/healthywater/hygiene/.

Methods adequate to purify public water supplies include chlorination, sedimentation, and filtration. Inactivation of *Giardia* cysts by chlorine requires attention to multiple variables such as the chlorine concentration, water pH, turbidity, temperature, and contact time. These variables cannot be controlled appropriately in all municipalities and are almost impossible to control in swimming pools and other water venues.[124–127] People should avoid swallowing recreational water; drinking water from shallow wells, lakes, rivers, streams, ponds, and springs; and drinking untreated water during community-wide outbreaks caused by contaminated drinking water. Travelers to endemic areas are advised to avoid drinking untreated water and uncooked foods that might have been grown, washed, or prepared with water that potentially was contaminated.

Purification of drinking water can be achieved by heating the water to a brisk boil for at least 1 minute or by using a filter that has been tested and rated by the National Safety Foundation (NSF) standard 53 or NSF standard 58 for cyst removal. Filtered water will need additional treatment to kill or inactivate bacteria or virus. Treatment with halazone for at least 30 minutes, saturated crystalline iodine, or similar chlorine and iodine preparations may be less effective against *Giardia* than boiling or filtering because they are affected by temperature, pH, and cloudiness of the water.[124,127] Additional information about water purification including use of water filters can be found at www.cdc.gov/travel/foodwater.html/ or at www.cdc.gov/crypto/gen_info/filters.html/.

Key Points

Diagnosis and Management of Infections With *Giardia intestinalis*

Microbiology

- Flagellated protozoan

- Humans strains are included in 2 of 8 specialized genetic groups called *assemblages.*
- After ingestion of infectious cysts, excystation occurs in the proximal small intestine, releasing trophozoites that attach to intestinal epithelium.

Epidemiology

- Distributed globally
- Detected in all classes of vertebrates including domestic and wild animals
- Most commonly diagnosed enteric parasite in the United States
- Person-to-person, foodborne, and waterborne transmission occur
- Nationally notifiable disease

Clinical Features

- Infection can be asymptomatic, acute, or chronic with failure to thrive or persistent intestinal symptoms.
- Chronic symptomatic giardiasis can occur in people with certain immune deficiencies.

Diagnosis

- Detection of cysts or trophozoites in stools or duodenal fluid by microscopy
- Detection of soluble stool antigen by direct fluorescent antibody testing, enzyme immunoassay, or immunochromatogenic assay
- Polymerase chain reaction can be used to subtype *Giardia.*
- Serologic tests not used in routine diagnosis

Treatment

- Several drugs are available in the US, but tinidazole, nitazoxanide, and metronidazole are the drugs of choice.

Prevention

- Avoidance of water and food that might be contaminated, use of appropriate hand hygiene, and avoidance of swimming venues by children (and others) with diarrhea

- Purification of drinking water when hiking

- A vaccine is not available.

Cystoisospora (*Isospora*) and *Cyclospora* Species

Mohammed Nael Mhaissen, Patricia M. Flynn

Cystoisospora belli (formerly *Isospora belli*) has been renamed and included in the *Cystoisospora* genus. Both *C. belli* and *Cyclospora* spp. infect the small intestine and have been implicated in diarrheal disease. *C. belli*, which first was linked with disease in 1915, is believed to infect only humans.[1] Prior reports of diarrhea associated with "Cyanobacteria-like" or "coccidian-like" bodies in stools are now thought to have been caused by *Cyclospora* spp.[2,3] Interest in *C. belli* and *Cyclospora* has increased because of their association with the human immunodeficiency virus (HIV) epidemic and identification in waterborne and foodborne outbreaks, respectively.

Pathogens

Both *C. belli* and *Cyclospora cayetanensis* are intestinal coccidia of the phylum Apicomplexa. Noninfectious, unsporulated oocysts are passed in stools. Sporulation outside the host usually occurs within 7 to 15 days under ideal conditions (23°–27°C). When sporulation occurs, oocysts presumably become infectious to a susceptible host. *C. belli* can be distinguished from *Cyclospora* spp. by their size and the number of sporozoites in each sporocyst; *C. belli* have four sporozoites per sporocyst, compared with two sporozoites per sporocyst in *Cyclospora* spp.[1,2]

Epidemiology

C. belli infection is endemic in developing countries, especially in South America and Africa, because of poor sanitation, and in tropical and subtropical climates.[1] The organism has been reported as an etiologic agent of traveler's diarrhea in visitors to endemic areas and has been implicated in outbreaks in facilities for handicapped people.[1,4–8] Cystoisosporiasis has been documented in 15% of patients with the acquired immunodeficiency syndrome (AIDS) in Haiti but in <0.2% of patients with AIDS in the United States.[1] The presence of the organism almost always is associated with symptoms, and in the United States, reports of *C. belli* usually involve persons with AIDS. Infection in other immunocompromised populations, such as patients with cancer or patients receiving immunosuppressive medications, also has been reported.[9–11]

C. cayetanensis infections have been documented in both immunocompetent and immunocompromised hosts worldwide.[9–15] Epidemiologic studies in Peru and Nepal have demonstrated seasonal variation in the number of infections. In Peru, infections peaked between April and June.[2] In Nepal, no infections were diagnosed in the cooler, dry months between December and April.[12] Asymptomatic carriage of the organism has been noted in Peruvian natives.[2] However, in studies of tourists and foreign residents in Nepal, identification of the organism was always associated with diarrhea.[12]

Infection with *C. belli* and *Cyclospora* follows ingestion of mature oocysts.[6] Because sporulation occurs outside of the host, direct person-to-person transmission does not occur. Both *Cystoisospora* and *Cyclospora* have been linked to contaminated food and water, although *Cyclospora* is more frequently associated with food and waterborne sources. The first reported outbreaks of diarrheal illness associated with *Cyclospora* in the US occurred among employees and physicians in a Chicago hospital in 1990; stagnant water supplied to the physicians' dormitory was implicated.[16] Multiple outbreaks associated with contaminated foods, including berries, lettuce, snow peas, and basil, and water have been reported.[17–26]

Clinical Manifestations

Clinical signs and symptoms associated with either organism usually are evident within 1 week (range, 3–14 days) of infection. Diarrhea is the hallmark of infection for both organisms but may not be the presenting or predominant symptom for patients with *Cyclospora* infection.[1–3,6,19,27] Described as profuse, foul-smelling, and watery, diarrhea can result in dehydration or weight loss. Affected people can have intermittent, crampy abdominal pain, flatulence, nausea, vomiting, and anorexia. Biliary tract disease also has been reported.[28–30] Diarrhea can alternate with constipation in cyclosporiasis.[3] Fever is more common in cystoisosporiasis. In immunocompetent hosts, both organisms produce a self-limited infection, although diarrhea can persist for several weeks. Chronic diarrhea is common in HIV-infected patients, and onset of diarrhea can be more insidious than in immunocompetent hosts.[1,27] In patients with HIV infection, symptoms and shedding of oocysts can continue indefinitely. In immunocompetent hosts with self-limited disease, shedding can persist for several weeks after resolution of symptoms. Bouts of acute and relapsing diarrhea also are described.[16]

Laboratory Findings and Diagnosis

Infection with either organism is best diagnosed through identification of oocysts in stained smears of stool. Although staining frequently is variable, both organisms can be identified with use of a modified acid-fast stain.[15] *Cyclospora* also are detectable with phenosafranine stain and through autofluorescence.[2] Oocysts are round and resemble *Cryptosporidium*, but *Cyclospora* are twice the size of *Cryptosporidium* (Fig. 266.1). *Cyclospora* do not stain with the monoclonal antibody specific for *Cryptosporidium* spp.[2,18] *C. belli* oocysts are oval, measuring 23 to 33 µm long by 10 to 19 µm wide (Fig. 266.2).[1] Polymerase chain reaction and flow cytometry have been used to detect both

Cyclospora and *C. belli* in clinical and environmental samples, but these tests are not available commercially.[31–35] Serologic assays are not available for detection of antibody to either organism.

Small bowel biopsy reveals pathologic changes, including blunting and atrophy of villi, acute and chronic inflammation, and hyperplasia of crypts.[6,7] The extent of histopathologic changes correlates with severity of clinical symptoms, including malabsorption.[2] Finally, peripheral eosinophilia is commonly seen in association with cystoisosporiasis and can indicate the possibility of this infection in the right settings.[36]

Treatment

C. belli is effectively treated with trimethoprim-sulfamethoxazole (TMP-SMX).[37] In a study of administration of oral TMP (160 mg) and SMX (800 mg) four times daily for 10 days and then twice daily for 3 weeks to adults who were HIV-infected, diarrhea ceased within 2 days in all patients; however, relapse occurred in 47%.[27] In another study, initial therapy with TMP (160 mg) and SMX (800 mg) four times daily for 10 days, followed by prophylaxis with either TMP (160 mg) and SMX (800 mg) three times a week or sulfadoxine (500 mg) and pyrimethamine (25 mg) given weekly was equally effective in eliminating diarrhea and preventing relapse in patients infected with HIV.[38] The recommended dose of TMP-SMX for children is 5 mg of TMP/kg/dose given twice daily for 10 days. In another study in adults, daily pyrimethamine (75 mg), alone or with folinic acid, followed by daily pyrimethamine at the reduced dose of 25 mg was effective in patients with adverse reactions to sulfonamide drugs.[39] An acceptable dosing regimen for children who are unable to tolerate TMP-SMX would include pyrimethamine 1 mg/kg plus folinic acid 10 to 25 mg by mouth once daily for 14 days. Nitazoxanide and ciprofloxacin also have been reported to be effective.[40,41] Additionally, immune reconstitution associated with initiating combination antiretroviral therapy in HIV-infected patients with cystoisosporiasis is indicated.[37]

Similar success with TMP-SMX treatment has been reported in *Cyclospora* infections.[19,37,42–44] Patients with HIV were treated successfully with a regimen of 160 mg TMP plus 800 mg SMX, given four times a day for 10 days; diarrhea resolved in all patients within 2.5 days. Recurrence was prevented with secondary prophylaxis consisting of TMP-SMX administered thrice weekly.[44] Treatment with 160 mg TMP plus 800 mg SMX, administered twice daily for 7 days, successfully eradicated the organism from immunocompetent hosts in Nepal.[43] There are few studies of treatment in children; TMP-SMX, 5 mg of TMP/kg/dose given twice daily for 10 days, would be an acceptable regimen. Ciprofloxacin is acceptable therapy for patients who cannot tolerate TMP-SMX.[29,40] Nitazoxanide also has been proposed as effective therapy in patients with sulfa intolerance.[29,45]

As with all causes of diarrhea, supportive care, including replenishment of fluids and electrolytes, is essential.

Prevention

To date, nosocomial spread has not been reported. Nonetheless, careful handwashing by both the caregiver and the patient is recommended. Travelers to endemic areas should avoid untreated water as well as consumption of unpeeled fruits and vegetables, all of which can be contaminated.

Leishmania Species (Leishmaniasis)

Moshe Ephros, Naomi E. Aronson

Description of the Pathogen

The genus *Leishmania* comprises vector-borne protozoan parasites that cycle asexually between the digestive tract of the sand fly as a motile flagellated promastigote and, in a wide range of vertebrate hosts (e.g., rodents, canids, hyrax, humans), as an immotile intracellular amastigote (Fig. 267.1). Infection can therefore be either zoonotic or anthroponotic (when humans serve as reservoir) and occurs when a female sand fly (Fig. 267.2) takes a blood meal and introduces infective metacyclic promastigotes into a vertebrate's skin, where they are phagocytosed by macrophages and dendritic cells. Parasites replicate in the reticuloendothelial system in phagolysosomes while evading or disabling host defenses; host cells ultimately rupture and release amastigotes, which infect other phagocytic cells (Fig. 267.3). In addition, parasites disseminate through regional lymphatics and vascular channels.

The genus *Leishmania* is divided into two subgenera: *Leishmania*, distributed worldwide, and *Viannia*, limited to Central and South America (Table 267.1). Species can be categorized by parasite isoenzymes (zymodemes),[1] but current taxonomy increasingly relies on molecular analysis with species-specific oligonucleotide primers or mass spectrometry.[2]

Pathogenesis and Immunity

The virulence of a specific parasite for a specific host depends on a large number of interacting variables.[3] Parasite factors include inoculum size, genetically determined subspecies or strain variability that influences pathogenicity, and tissue tropism (e.g., risk for mucosal leishmaniasis, [ML] with *L.V. braziliensis*), which varies geographically.[4–6] Host factors include immune defects, nutritional status, extremes of age, and comorbidities.[7–11] Sand fly factors such as the maxadilan content of *Lutzomyia* saliva, a vasodilatory protein that also otherwise facilitates infection, are also associated with pathogenicity. Host immune responses acquired before infection directed against sand fly saliva impede *Leishmania* infection.[12,13]

Despite the fact that each *Leishmania* sp. usually causes a specific clinical syndrome (i.e., visceral leishmaniasis [VL], cutaneous leishmaniasis [CL], or ML), any species can cause other clinical syndromes. Infection occurs when the parasite is able to overcome or inhibit protective host cell−mediated immunity, expressed predominantly by a Th1 response driven by interferon γ (IFNγ), interleukin-2 (IL-2), and IL-12.[14] At the cellular level, IFNγ induces macrophage L-arginine−dependent nitric oxide and superoxide production.[3] A predominantly Th2 host response or *Leishmania* inhibition of host Th1 response usually facilitates infection. Abnormal host cell−mediated immunity response increases infection rates, disease severity, and atypical manifestations. Histopathology of affected tissue will show mixed acute and chronic infection and granulomas with epithelioid giant cells, with or without parasites. With clinical cure, the host develops species-specific immunity dependent, in part, on lifelong persistence of viable intracellular parasites and a Th1 cellular response. Memory T lymphocytes, even in the absence of persistent parasites, and $CD8^+$ T lymphocytes also may play a role.[15–17] In VL, a positive skin test response is present concomitantly with clinical cure. Antibodies directed against the parasite are not protective, although their presence may aid in diagnosis.[18–20]

Epidemiology

Leishmaniasis is a complex of diseases transmitted by a sand fly bite. Human infection is caused by more than 23 species of *Leishmania* with >90 sand fly subspecies that are proven or likely vectors.[20a] Proven vectors of human disease are the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World (see Table 267.1). Leishmaniasis generally is a zoonosis with ecologic links between a specific animal reservoir and sand fly subspecies. Anthroponotic transmission is seen in urban *L. tropica* cutaneous infections in Afghanistan.[21] Anthroponotic transmission of *L. donovani* visceral infection occurs in India, Nepal, and Bangladesh, whereas mixed zoonotic and anthroponotic *L. donovani* transmission occurs in East Africa.[22–28] Female sand flies are usually nocturnal feeders, but if disturbed, they may feed during the day. Transmission is seasonal, and sand flies are poor fliers, so hyperendemic transmission areas occur close to mammalian reservoirs. Other uncommon modes of transmission include intravenous drug use, blood transfusion, organ transplantation, occupational needle stick, laboratory accident, maternal-fetal transmission, and sexual transmission.

Leishmaniasis affects about 12 to 15 million people worldwide, 75% of cases being cutaneous disease. Leishmaniasis is a neglected tropical disease; globally it is strongly associated with social determinants of poverty, and limited resources are available for disease control, diagnosis, and treatment. The World Health Organization estimates an annual incidence of 1.3 million cases of CL and 200,000 to 400,000 new VL cases, with 20,000 to 40,000 VL deaths per year.[28] VL is second only to malaria as a parasitic cause of death in the world. A disproportionate number of children compared with immunocompetent adults are infected with VL (>50% cases) and Old World CL.[29] Contributing factors include higher rates of malnutrition, lack of prior exposure and acquired immunity to parasite and sand fly saliva, and a less mature immune system. Worldwide migration, poverty, lack of adequate control measures, and immunosuppressing conditions (e.g., HIV, transplantation, cancer chemotherapy, and biologic immunomodulator therapy) are driving an increasing incidence of VL.[30] Eighty percent of *L. donovani* VL occurs in northeastern India, southeastern Nepal, and Bangladesh (Fig. 267.4).[28] VL due to *L. infantum* occurs primarily in the Mediterranean, Middle East, Afghanistan, Iran, Pakistan, Iraq, and Brazil.[20a,23] More than 70% of CL cases are reported from 10 countries: Syria, Peru, North Sudan, Iran, Ethiopia, Costa Rica, Colombia, Brazil, Algeria, and Afghanistan (see Fig. 267.4C and D).[28]

Sporadic leishmaniasis can affect people of all ages and can occur when susceptible people (i.e., tourists, migrants) enter an endemic area. Outbreaks have been associated with movement of large numbers of susceptible people (i.e., agricultural or refugee settlements, military personnel) into endemic areas or may be related to population upsurges of reservoir hosts.[31,31a] Among travelers, imported CL cases have increased since the mid-2000s. CL is one of the most common dermatologic conditions (18% of skin diseases) in returning travelers from Central and South America, especially Bolivia, Costa Rica, and Peru.[32,33] In a British report, Old World CL was associated with Mediterranean coastal travel and mainly *L. infantum* CL; New World CL was primarily due to *Viannia* spp. in backpackers or soldiers.[34]

Clinical Manifestations

Cutaneous Leishmaniasis

CL should be suspected when a person has a chronic, usually painless, nodular or ulcerative lesion on exposed skin and a history of residence in or travel to an endemic area. Nuances of childhood cases are shown in Box 267.1. The incubation period after sand fly bite is between 2 weeks and many months, sometimes even years. An erythematous macule appears first, gradually becoming an inflammatory papule with progressive induration (with or without superficial scaling). As inflammation increases the papule becomes nodular, often ulcerating, and with a raised border. Lesion morphology is highly variable and also includes plaques and psoriasiform or verrucous lesions. Size can vary from <1 cm to 10 cm. Satellite lesions, hyperkeratotic eschars, fibrinous exudates, sporotrichoid (lymphangitic) spread, and regional lymphadenopathy also occur. Lesions usually are painless unless secondarily infected.[35,36] Resolution with scarring (usually described as paper-like with thin skin) is the rule, taking from months to years. Facial lesions can be quite disfiguring and may involve mucosae contiguous with skin (sometimes resembling ML). Lesions overlying joints may heal poorly.

Pediatrics-Specific Leishmaniasis Points

General

Children comprise a disproportionately larger part of the total disease burden, including visceral leishmaniasis (VL) due to *L. infantum* (syn. *chagasi*), and some cutaneous leishmaniasis (e.g., Old World cutaneous leishmaniasis [CL]).

Children have fewer comorbidities and tolerate systemic therapy better than adults, with fewer and milder adverse effects.

Systemic treatment of children's leishmaniasis may yield lower cure rates than adults due to pharmacokinetic differences (e.g., increased drug clearance).

Scarring and disfigurement can result in social stigmatization that may be highly damaging, especially but not exclusively, for young women and girls.

For prevention of sand fly bites, use recommended insect repellents and permethrin-treated fine-mesh bed nets and clothes.

Cutaneous Leishmaniasis

Children have more facial lesions than do adults.

Most children in Old World-endemic areas are infected at 2–3 years of age.

Local therapy (e.g. thermotherapy, intralesional injection) often is painful or traumatic and may require multiple sessions; anesthesia or sedation may be required.

Visceral Leishmaniasis

Mortality of treated VL in endemic countries ranges from 3% to 10%, with a somewhat better prognosis for children. However, children younger than 6 months and adults 65 years and older have the highest mortality rates.

Asymptomatic or oligosymptomatic infections (which can mimic many other pediatric diseases) occur variably by location and may or may not progress to overt disease.

Congenital infection occurs rarely.

Hemophagocytic lymphohistiocytosis (HLH) can be induced by VL, and VL should be considered in any patient with HLH residing in or having visited a VL-endemic area.

The sensitivity of bone marrow aspiration for diagnosing VL in children is approximately 90%, better than for adults (40%–70%).

Amphotericin B products may have a need for pediatric specific dosing regimens in VL.

Miltefosine is problematic for young children because it is only available as capsules, weight-based dosing for small children may be insufficient, and it is not yet approved by the US Food and Drug Administration for children younger than 12 years.

CL in the normal host most often is localized, but the interplay between host and parasite can lead to a wide spectrum of manifestations, such as inflammatory oligoparasitic lesions (e.g., leishmaniasis recidivans) or hyperparasitic, less inflammatory lesions (e.g., diffuse CL) (Fig. 267.5). CL in immunocompromised people, especially in those with abnormal cell-mediated immunity, may have an especially prolonged course, more severe or unusual cutaneous lesions, or occasionally become visceralized.[37,38]

The multiple clinical syndromes associated with the many geographically diverse species of *Leishmania* are listed in Table 267.1. Old World CL occurs widely in the Middle East, the Mediterranean, Asia, Africa, and the Indian subcontinent. The parasites responsible usually are *L. major, L. tropica,* and *L. aethiopica,* but also *L. infantum* and *L. donovani*. Leishmaniasis recidivans is almost always due to *L. tropica*, mostly on the face, usually at the edge of a healed CL scar. The lesions include nodules, papules, and shallow ulcers and can wax and wane over years, are difficult to treat, and are oligoparasitic and inflammatory.[39] ML associated with Old World CL and VL in the Sudan due to *L. major* or *L. donovani* or due to *L. infantum* in immunocompromised people has been reported.[40]

New World CL is widespread in Latin America and is caused by a number of species from both *Viannia* and *Leishmania* subgenera (see Table 267.1). In addition, *L. infantum* (syn. *chagasi*) can also cause cutaneous disease. As in Old World CL, the primary manifestation is localized CL, but diffuse CL does occur (*L. mexicana* and *L. amazonensis*).[41] *L. V. braziliensis*, especially south of Costa Rica, is associated with ML, particularly in Bolivia, Brazil, and Peru. To a lesser extent, *L. V. panamensis, L.V. guyanensis,* and *L. amazonensis* also are associated with ML.

Mucosal Leishmaniasis

ML generally occurs in 1% to 5% of people with New World CL due to species associated with ML. Months to years after New World CL, a patient can experience symptoms related to metastatic mucosal involvement of the nose, mouth, pharynx, and larynx, including nasal stuffiness, epistaxis, septal perforation or nasal collapse, palatal dysfunction or vocal cord involvement, and airway compromise or obstruction. Otolaryngologic examination may be required to aid in diagnosis.

ML local changes can be predominantly hypertrophic (espundia, or sponge-like) or ulcerative (destructive), with oligoparasitic, highly inflammatory lesions. Risk factors include male sex, young adulthood, severe malnutrition, and original CL lesion duration of >4 months.[42–45]

CL and ML must be included in the differential diagnosis of any persistent or progressive skin or mucosal lesion in someone having been in an endemic area. Diseases to be considered in the differential diagnosis of CL include cutaneous tuberculosis, nontuberculous mycobacteria (i.e., leprosy, syphilis, yaws, tropical pyoderma), fungal infections (e.g., blastomycosis, chromoblastomycosis, lobomycosis, sporotrichosis), sarcoid, lupus vulgaris, and skin neoplasia. For ML, consider *Mycobacterium tuberculosis,* syphilis, yaws, paracoccidiomycosis, histoplasmosis, sarcoid, lethal midline granuloma, certain lymphomas, skin neoplasia, and rhinosporidiosis.

Visceral Leishmaniasis

VL (also known as *kala-azar*) is caused by *L. donovani* in East Africa and northeastern India, Nepal, and Bangladesh (see Fig. 267.4). *L. donovani* causes the most severe VL syndrome with high mortality when untreated and often manifests as the pentad of fever, weight loss, hepatosplenomegaly, pancytopenia, and hypergammaglobulinemia. In the Mediterranean, South America (mainly Brazil), Middle East, and South West Asia, *L. infantum* (syn. *chagasi*) causes VL in children and immunocompromised hosts. Much less commonly, other *Leishmania* spp. associated with VL include *L. tropica* and *L. amazonensis*.[46,47]

Parasites persist inside macrophages throughout the reticuloendothelial system, regardless of treatment. This allows for later reactivation in situations in which cell-mediated immunity is attenuated. Overt symptomatic VL is unlikely to resolve without treatment, and mortality is 75% to 95%; however, mortality is reduced to 3% to 10% with treatment. Asymptomatic and subclinical infections are common, reflecting an appropriate host immune response to *Leishmania*. The ratio of asymptomatic to symptomatic VL varies depending on the region, ranging from 30 : 1 to 100 : 1 in Western Europe and North America, to 6 : 1 in Brazil, and to 4 : 1 in Bangladesh.[48–51] Most of these subclinical or asymptomatic infections seem to be self-resolving, but in India and Nepal risk for progression to overt VL was seen.[52]

The onset of nonspecific VL symptoms is insidious with an incubation period that is usually 3 to 8 months but can range from weeks to years.[53] In imported VL, adults are more likely than children to have a long duration of symptoms before treatment is initiated.[54] Occasionally, a small macule, papule, or ulcer may precede VL symptoms. These lesions show amastigotes on analysis but may be resolved by the time symptomatic VL develops.[55] The signs and symptoms of children and adults with VL do not significantly differ.[56–59]

Fever is common (95%−100%) and can be constant, intermittent, or recurrent. Classically, a twice-daily fever pattern has been associated with VL. Other frequent symptoms are lethargy, anorexia, weight loss, and abdominal distention. Less common symptoms include rigors, cough, diarrhea, jaundice, bleeding, and bruising.[30,58,60–69] Splenomegaly occurs in 95% to 100% of patients and can be massive. Generally the spleen is described as nontender, firm, or even hard in texture, although in rapidly progressive cases it may feel soft. HIV patients have a somewhat lower frequency of splenomegaly (80%).[70] Hepatomegaly is less frequently observed (66%−95%), and enlargement is less than the spleen. Lymphadenopathy is reported in East African VL but is seen less commonly in other geographic settings.[27] In Indian *L. donovani* infection specifically, hyperpigmentation (darkening in light-skinned persons) of the hands, feet, forehead, and abdomen led to the Hindi name *kala-azar* (black fever). Other less common findings are pallor, edema, bleeding, ascites, malnourishment, and intercurrent infections (bacteremia, bronchopneumonia, gastroenteritis, otitis media, skin infections). Immunocompromised patients may have additional unusual presenting signs in the gastrointestinal tract (chronic diarrhea, esophageal constricting lesions, tongue lesions), disseminated skin lesions, and mucosal or lung (pleural effusion) involvement.[71]

Clinical laboratory abnormalities vary among the published pediatric clinical series but include pancytopenia, anemia (usually normocytic-normochromic), leukopenia, neutropenia, eosinopenia, thrombocytopenia, low serum albumin, and hypergammaglobulinemia. Renal involvement has been reported and includes urinary concentrating defects, immune complex interstitial nephritis, minimal change glomerulonephritis, white and red blood cells in urine, proteinuria, and decreased glomerular filtration rate.[72–74] Mildly elevated serum hepatic transaminases and sometimes hyperbilirubinemia may be seen. The sedimentation rate often is 50 to 60 mm/hr.

The differential diagnosis of VL is broad, essentially that of chronic fever and splenomegaly. A more acute clinical course can suggest typhoid fever, malaria, acute schistosomiasis, cytomegalovirus, hepatitis, American trypanosomiasis, and amebic liver abscess. Chronic diseases to consider include leukemia and lymphoma, brucellosis, miliary tuberculosis, subacute bacterial endocarditis, histoplasmosis and other disseminated endemic fungal infections, tularemia, hyperreactive malarial splenomegaly syndrome, portal hypertension (e.g., schistosomiasis), and Felty syndrome.

Hemophagocytic lymphohistiocytosis (HLH) is a complication of VL, especially in children, and leads to diagnostic confusion. VL always should be considered in patients with HLH who may have been exposed in VL endemic regions. Treatment of VL usually will resolve signs and symptoms and permit avoidance of potentially harmful HLH treatments and investigation.[75–78]

Risk factors associated with a poor outcome or death include prolonged illness, jaundice, severe anemia, malnutrition, age <1 year, mucosal bleeding, neutropenia <500/mm^3, platelets <50,000/mm^3, concomitant infections, gastrointestinal symptoms.[27,79–81] A prognostic scoring system for children with VL has been published.[82] Death is generally due to complications of concomitant infections (during neutropenia), bleeding, malnutrition, and occasionally hepatic failure. HIV-infected patients have poor response to treatment, higher relapse rate, and higher mortality. Tuberculosis increases the risk for mortality from VL, even in the absence of HIV infection.[79,83]

Congenital VL is reported infrequently, when a mother has traveled to an endemic area during pregnancy. In one case, the placenta revealed amastigotes, but VL usually was diagnosed in the infant 7 to 16 months after birth.[84,85]

Diagnosis

When leishmaniasis is suspected clinically, diagnosis should be attempted by a variety of parasitologic and adjunctive immunologic tests. Tissue from lesions or potentially infected organs should be tested for parasites by smear, histopathology, parasite culture, or molecular testing.[86] Biopsy (as opposed to aspirate or scraping) is not required often but may be particularly useful when the diagnosis is not clear or when atypical disease is encountered, thus allowing for pathologic evaluation as well for culture and molecular testing. More information about testing at reference laboratories is available at http://www.cdc.gov/parasites/leishmaniasis/health_professionals/in

Under oil immersion, hematoxylin-eosin and Wright-Giemsa stains show intracellular amastigotes with their characteristic rod-shaped kinetoplast (see Fig. 267.3). In vitro culture (using Schneider or Novy-MacNeal-Nicolle media) should be attempted despite a relatively lengthy time to positive culture (i.e., days to weeks). Molecular testing for parasitic DNA is sensitive (~95%) and permits determination of species.[21,87–90]

For CL, the ulcer should be clean or debrided, and tissue should be obtained by scraping or brushing the base or edge. If there is no ulcer, tissue should be obtained by aspirate, skin snip, punch, or shave biopsy. Speciation by isoenzyme analysis of cultured parasites or by molecular analysis of infecting *Leishmania* is important for therapeutic decision making, particularly in CL (e.g., differentiating *L. mexicana* and *L. braziliensis* or *L. tropica* from *L. major*).[86] For ML, specimens are obtained similarly as for CL except that tissue may need to be obtained by an otolaryngologist. In addition to histopathology, polymerase chain reaction (PCR) and culture should be performed.

For VL, tissue aspirate or biopsy should be performed. Although a splenic aspirate provides high sensitivity (~95%), this usually is not performed in North America because of the risk for hemorrhage.[86,91] Bone marrow aspiration usually is performed but is less sensitive overall (40%–90%), although sensitivity in children is 90%.[29,63,64,68] Sampling of liver, enlarged lymph nodes, whole blood, or buffy coat also should be considered.

In the severely immunocompromised patient, parasites can be located in atypical sites such as intestinal mucosa, lung, and buffy coat.[71,92–94] In addition, quantitative PCR may prove helpful in monitoring response to therapy or diagnosing relapse of disease.[89,95]

When VL is suspected, testing for antileishmanial antibodies (e.g., rK39) by enzyme immunoassay, immunofluorescence assay, or agglutination assay can be helpful. Rarely, with strong clinical suspicion, antibodies alone might be considered sufficient to make a presumptive diagnosis and to initiate therapy. Antibody tests generally are not useful in the diagnosis of CL or ML.[96–98]

Treatment

There is no single, effective treatment that can cover all *Leishmania* spp. and syndromes. Additionally, clinical healing, even with treatment, is not always associated with a sterile cure. The goals of treating CL and ML are to accelerate healing and to prevent metastatic infection, scarring, and relapse; the goal of treating VL is to prevent mortality. Treatment should be tailored to the individual patient, including considerations of parasite species, the geographic region where infection was acquired, host comorbid conditions and immune status, and patient preferences. US clinical practice diagnostic and treatment guidelines are available.[98a]

Cutaneous Leishmaniasis

Self-healing is typical for CL after a variable number of months depending on species (e.g., *L. major*, 2–6 months; *L. mexicana*, 3–9 months; other species, 6–24 months).[99] The patient should be involved in decisions about watchful waiting for spontaneous healing of lesions with frequent follow-up and reassessment as well as local wound care. In general, CL is treated with local therapy *except* when the following complicating factors are present: (1) infection with species that can cause ML *(L.V. braziliensis, L.V. guyanensis, L.V. panamensis),* especially if acquired in the mucosal belt of Peru, Bolivia, and Brazil; (2) immunocompromised host; (3) complicated forms of CL such as leishmaniasis recidivans, diffuse cutaneous leishmaniasis, disseminated cutaneous leishmaniasis, and *L. aethiopica*; (4) clinical failure of initial local therapy; (5) size, location, or number of lesions not feasible for local therapy; (6) more than four lesions >1 cm; (7) an individual lesion ≥5 cm; (8) lesions in cosmetically sensitive locations (i.e., face, ear, finger, genital region, toes); and (9) subcutaneous nodules in lymphatic drainage route or large regional adenopathy. The treatment of CL with complicating factors generally is systemic oral or parenteral therapy.

All CL that is ulcerative is a wound. Secondary infection (purulence or surrounding cellulitis) should be treated; debridement of overlying crust or necrotic debris should be performed down to a clean base if any purulence is noted. Ulcerative lesions should be washed with mild soap and water daily, then covered with a thin layer of petrolatum-based ointment after bathing. Cosmetic surgery and skin grafts should be postponed for 12 months after successful CL healing to avoid reactivation (including at sites remote from the initial lesion).[100]

Local therapy is preferred for Old World CL and may be useful in some New World CL caused by *Leishmania* spp. unlikely to be associated with dissemination. This recommendation is because local therapy generally is sufficient in these circumstances, speeds healing, is less toxic, and is less expensive compared with systemic therapies. Local therapy includes modalities of heat and cryotherapy, intralesional amphotericin or pentavalent antimonial drugs, photodynamic treatment, and paromomycin-based topical cream or ointment.[101,102] For young children, some treatments can be painful and may require general anesthesia.

Topical paromomycin is a local therapy mainly studied in ulcerative lesions due to *L. major* or non−ML-associated Central American *Leishmania* spp. In Israel, topical 15% paromomycin with 12% methylbenzethonium chloride (Leshcutan ointment) was associated with healing in only 35% to 40% of *L. tropica* lesions. The vehicle appears to be important for efficacy, and not all preparations are equivalent.[103] WR 279,396 (a cream of 15% paromomycin and 0.5% gentamicin) is in development; efficacies of 81% to 94% were seen in randomized controlled trials.[104–106]

Systemic therapy includes both oral and parenterally administered drugs. The oral drugs used for CL include miltefosine and the azoles (fluconazole and ketoconazole). Miltefosine was approved by the US Food and Drug Administration (FDA) in 2014 for the treatment of CL due to *L.V. braziliensis*, *L. V. guyanensis*, and *L.V. panamensis*. A recent review summarizes the evidence base for miltefosine, but salient facts include regional differences in efficacy for CL, especially with *L. V. braziliensis*; resistance has been described; and it is teratogenic.[107] The target dosage is 2.5 mg/kg/day for 28 days (Table 267.2). The azole drugs have limited efficacy, and treatment failure is common. Azoles may be active for *L. major*, *L. mexicana*, and some *L.V. panamensis* infections.[108,109]

[f] There is no preferred secondary prophylaxis regimen. Options include L-AmB, 3−5 mg/kg every 3−4 weeks; alternate is pentamidine, 4 mg/kg (no more than 300 mg) every 3−4 weeks.

CDC, Centers for Disease Control and Prevention; ECG, electrocardiogram; FDA, US Food and Drug Administration; IM, intramuscular; IND, investigational new drug (application); IV, intravenous; MA, meglumine antimoniate; PO, oral; SSG, sodium stibogluconate; USAMMDA, US Army Medical Materiel Development Activity.

Parenteral therapies include amphotericin products (deoxycholate and lipid compounds) and the pentavalent antimonial drugs (i.e., sodium stibogluconate and meglumine antimoniate). Sodium stibogluconate is not approved by the FDA but is available through an investigational new drug protocol from the Centers for Disease Control and Prevention. Meglumine antimoniate can be obtained by investigator sponsored investigational new drug request. Pentavalent antimonial drugs generally have good efficacy in the treatment of CL, but there is known clinical nonresponsiveness in CL cases acquired in Madidi National Park, Bolivia and Manu National Park and Porto Maldonado, Peru. Amphotericin B deoxycholate is effective treatment for CL, but its use is constrained by toxicity and duration of treatment; off-label use of liposomal amphotericin circumvents this, and several case series suggest 70% to 80% efficacy using the FDA-approved VL regimen total dose.[110–112]

Mucosal Leishmaniasis

The longstanding treatment of ML has been pentavalent antimonial drugs (20 mg/kg/day given intravenously or intramuscularly) for 28 days with or without pentoxifylline.[113] A recently published case series suggested that liposomal amphotericin at a total dose of 30 mg/kg was associated with 88% efficacy.[114] Miltefosine is indicated for the treatment of ML at the oral dose of 2.5 mg/kg/day (maximum, 150 mg/day in divided doses) for 28 days; however, miltefosine only has been studied in Bolivian ML, and further clinical experience will elucidate whether it has broad geographic efficacy.

Visceral Leishmaniasis

All patients with symptomatic VL should be treated because untreated VL is associated with fatality, usually due to bleeding or bacterial infections. Treatment includes antiparasitic therapy as well as nutrition, control of bleeding, antibiotics for secondary infection, and blood transfusion for severe anemia. All VL patients should be assessed for immunocompromising conditions (e.g., HIV infection) because this can affect treatment and management.

Drugs for the treatment of VL include liposomal amphotericin, sodium stibogluconate, meglumine antimoniate, parenteral paromomycin, and oral miltefosine. In North America, the treatment of choice is liposomal amphotericin B administered to immunocompetent patients at a dose of 3 mg/kg on days 1 to 5, 14, and 21. Immunocompromised hosts and VL from East Africa need higher doses and longer durations of treatment.

Clinical response using various systemic drugs varies by geographic area, with clinical resistance to pentavalent antimonial drugs frequent in north India and Nepal.[115,116] For VL acquired in India, Nepal, Bangladesh, or Bhutan, miltefosine or liposomal amphotericin is used at the FDA-approved regimen for *L. donovani*; however, several studies have suggested lower total doses may suffice for Indian VL.[117,118]

In contrast, higher doses of liposomal amphotericin are needed in East African *L. donovani* VL. Liposomal amphotericin doses of 30 mg/kg total dose were required, even higher in relapsed VL, and the World Health Organization now recommends an liposomal amphotericin total dose of 40 mg/kg in Africa.[119,120] In non–HIV-infected patients in East Africa, pentavalent antimonial drugs still perform well. The combination of parenteral pentavalent antimonials (20 mg/kg/day) and paromomycin (15 mg/kg/day) for 17 days showed similar efficacy to 30 days of pentavalent antimonial drugs.[121]

In Mediterranean and Brazilian *L. infantum* (syn. *chagasi*), liposomal amphotericin is effective and has less toxicity, has a shorter treatment duration, and is approved by the FDA for VL, compared with the stalwart treatment of pentavalent antimonials, which has been used for decades but is now relegated to second-line therapy. In Greek children, an abbreviated regimen of liposomal amphotericin (10 mg/kg/day for 2 days) was as effective as 30 days of pentavalent antimonials. However, the daily dose of 10 mg/kg carries some risk for severe hypotension.[122,123] Miltefosine has not been well studied in *L. infantum* VL.

Young children may have lower response rates to pentavalent antimonial treatment compared with older children and adults, possibly explained by an increased clearance rate and lower plasma exposure.[124,125] Children tend to tolerate pentavalent antimonials and amphotericin better than adults, with less side effects, perhaps owing to fewer medical comorbid conditions. Miltefosine is approved by the FDA only for children 12 years or older who weigh at least 30 kg. In addition, the smaller capsule of 10 mg was not approved, only the 50-mg capsule. The approved drug regimens are listed in Table 267.2. Studies of miltefosine in young children in South Asia and South America showed lower response rates, particularly persons receiving <2.5 mg/kg/day.[126,127]

Most VL relapses occur in the first 6 months of follow-up. Clinical findings are sufficient to assess relapse and correlate well with parasitologic responses. The patient's temperature should be monitored with defervescence expected within 1 week of treatment initiation. The spleen and liver decrease in size over a period of 3 to 6 months. Leukopenia and thrombocytopenia usually normalize within a month, but anemia may take 6 to 12 months to resolve.[123,128–130] Antibodies remain detectable for prolonged periods and are not useful for following; if symptoms do not resolve or relapse, then parasitologic confirmation should be sought.

Immunocompromised Host

Immunocompromised patients with CL generally are treated with systemic therapy, although there are limited reports to support treatment recommendations (see Table 267.2). Secondary prophylaxis is not used, and antiretroviral therapy should be initiated or maintained in HIV-infected patients.

In VL, liposomal amphotericin at a higher dose of 4 mg/kg given intravenously on days 1 to 5, 10, 17, 24, 31, and 38, for a total dose of 40 mg/kg, is recommended. In persons with HIV/AIDS, antiretroviral therapy should be optimized, and secondary prophylaxis (chronic maintenance therapy) should be given for $CD4^+$ cell counts until 6 months of immune reconstitution has occurred.[131] Immune reconstitution inflammatory syndrome occurs but appears to be uncommon. Combination treatment with miltefosine and liposomal amphotericin in India shows promise.[132] The pentavalent antimonial drugs are less well tolerated in HIV-infected patients, and mortality was higher than with liposomal amphotericin.[133]

In transplant recipients with VL, doses of immunosuppressive drugs should be decreased, and a recent case-control study suggested benefit from secondary prophylaxis[134] During treatment of CL and VL in patients receiving drug-induced immunosuppression (such as the TNFα-inhibiting drugs) decreased dosing or withdrawing (if possible) the immunosuppressing drug is recommended.[71,135] Persons with VL and other immunocompromising situations (e.g., hematologic malignancies, chemotherapies, biologic immunomodulators, or corticosteroids) should also receive systemic therapy, although data are restricted to case reports and small case series.[71]

Prevention and Control

Preventing leishmaniasis has not yet proved successful. There is no effective human vaccine or chemoprophylaxis.[14] Leishmanization, the purposeful infection with pathogenic *Leishmania* of noncritical body sites (e.g., buttocks) to achieve immunity in CL, thereby preventing destructive facial scarring, has been performed but is not recommended. Other approaches vary by the setting (e.g., endemic area vs. traveler, areas with zoonotic or anthroponotic transmission, animal reservoir, and vector type).[136–141]

For travelers, personal protection measures include use of insect repellents and insecticide-impregnated clothing and fine-mesh bed nets. In endemic areas, vector control using residual insecticides potentially is ecologically and individually deleterious (e.g., DDT), requires repeated spraying, leads to vector resistance, and is ineffective if transmission occurs in areas other than in and around buildings.[142] Destruction of sand fly eco-niches is usually environmentally unacceptable and, given their focal nature, is rarely effective.[136] Biologic sand fly control may have a role.

Proactive blood banking practices can prevent transfusion-related leishmaniasis, a rare but probably underestimated occurrence. Routine screening, especially in endemic areas, with the exclusion of positive blood, as well as instructing those with a history of visceral leishmaniasis (treated or not) to not donate blood may be appropriate. Using leukodepletion filters when administering blood products should exclude most intracellular parasites.[143] Routine serologic screening of organ donors from *Leishmania*-endemic areas is not recommended currently.[144]

In anthroponotic visceral leishmaniasis, case finding and treatment are very important yet probably insufficient because the parasite burden of undiagnosed asymptomatic persons and those with post–kala-azar dermal leishmaniasis will impede progress toward diminishing the overall local disease burden and the disruption of transmission. Where domestic dogs are reservoirs, immunization, when available, will help disrupt the life cycle. Until then, culling and use of collars or other topically applied insecticides or repellents are important tools.[136] When sylvatic canids are the reservoir, these modalities are impracticable other than attempting wild animal culling (not usually acceptable ecologically).

Until an effective vaccine is developed, a multidisciplinary approach may yield the best, yet still modest, results in the prevention and control of leishmaniasis.

Key Points

Leishmaniasis

Definitions, Pathogenesis and Epidemiology

- Sand fly–transmitted protozoan infection (1 genus, 2 subgenera, >23 species) causing a pleomorphic spectrum of clinical disease, with wide geographic distribution, multiple vectors, and mammalian reservoirs
- Major clinical syndromes include visceral (VL), cutaneous (CL), and mucosal (ML) leishmaniasis.
- Infection usually is lifelong; cure, either spontaneous (CL) or by treatment (CL, VL, ML), is clinically, not parasitologically, defined.
- Persons with defective cell-mediated immunity may have a higher risk for late reactivation and dissemination and may demonstrate atypical manifestations.
- Worldwide, ~350 million people are at risk in ~90 countries, with 12–15 million affected and 1–2 million new cases annually (~75% CL); proportionally more cases occur in children.

- VL is associated with significant mortality despite treatment (~10%); CL and ML cause significant morbidity (scarring and destructive naso-oropharyngeal lesions).

Diagnosis

- Consider leishmaniasis in people residing in or having visited an endemic area, with:
  - CL: persistent, usually painless, cutaneous nodules or ulcers
  - ML: inflammatory/destructive naso-oropharyngeal-laryngeal lesions, which can occur years after CL lesion healed
  - VL: febrile systemic illness, hepatosplenomegaly, and progressive pancytopenia
- Laboratory testing:
  - CL, ML: microscopy, culture, or PCR of lesion aspirate, scraping, or biopsy
  - VL: microscopy, culture, or PCR of bone marrow, liver, blood, buffy coat or lymph node; splenic aspirate is highly sensitive but carries risk for hemorrhage; serology may be useful adjunct

Management

Cutaneous

- Scarring, self-resolving infection, which usually heals over months to years and does not always require therapy

- Wound care for ulcerative CL lesions
- Treat to improve cosmetic and functional outcomes when lesions are large, numerous, or on sensitive areas, or the patient is immunocompromised or at risk for metastatic complications.
- Therapy can be local or systemic; some local methods may require sedation or anesthesia for children.

Mucosal

- Treat systemically to prevent mortality and tissue destruction
- Use pentavalent antimony, liposomal amphotericin B, or miltefosine

Visceral

- Treat systemically to prevent mortality
- Use pentavalent antimony, liposomal amphotericin B, or miltefosine
- Adjunctive therapy for secondary infections or bleeding
- Immunocompromised hosts may require posttreatment suppressive therapy.

Prevention

- No vaccine or prophylactic drug
- Sand flies usually bite dusk to dawn.

▪ Wear clothing that covers body

▪ Sleep indoors

▪ Use air conditioning

- Use insect repellents and permethrin-impregnated clothing and bed nets

- Vector and reservoir control may be used but are not highly effective in areas of anthroponotic leishmaniasis; active case finding and treatment are the basis for disease control.

Microsporidia

Mohammed Nael Mhaissen, Patricia M. Flynn

Before 1985, few human microsporidial infections had been reported. Since then, the number of cases has increased dramatically because of recognition of this pathogen in patients infected with human immunodeficiency virus (HIV). Although most reported infections have occurred in HIV-infected people, the organism is recognized increasingly as pathogenic in other immunocompromised populations (e.g., organ transplant recipients), as well as in immunocompetent hosts.[1–3]

Pathogen

Microsporidia are obligate, intracellular, spore-forming parasites that have been reclassified from protozoa to fungi (Fig. 268.1).[4] They are ubiquitous and infect most animal groups, including humans (Table 268.1). At least 15 species of microsporidia have been reported to be pathogenic in humans.[5,6] Microsporidia are characterized by spore size, nuclear configuration, and relationship between the organism and its host cell. Replication occurs within the cytoplasm of the host cell by both binary fission (merogony) and multiple fission (schizogony), and it culminates in spore production (sporogony). Maturing spores accumulate within a vacuole that eventually ruptures and releases the spores.[7] All microsporidial spores contain a complex tubular extrusion mechanism that injects the infectious substance (sporoplasm) from an infected cell into an uninfected host cell.[7]

Clinical Diseases Associated With Microsporidia

Organism	Disease
Anncaliia algerae	Myositis, disseminated disease, keratopathy, skin infection
Anncaliia connori	Disseminated disease, keratopathy
Anncaliia vesicularum	Myositis
Encephalitozoon cuniculi	Encephalitis, hepatitis, peritonitis, keratopathy, sinusitis, osteomyelitis, pulmonary disease, disseminated disease
Encephalitozoon hellem	Keratopathy, disseminated disease, sinusitis, pneumonitis, nephritis, urethritis, cystitis
Encephalitozoon intestinalis	Diarrhea, cholangitis, disseminated disease, nodular skin lesions, keratopathy
Enterocytozoon bieneusi	Diarrhea, cholangitis, pulmonary disease
Microsporidium africanum	Keratopathy

Microsporidium ceylonensis	Keratopathy
Nosema ocularum	Keratopathy
Pleistophora ronneafiei	Myositis, disseminated disease, sinusitis
Trachipleistophora hominis	Myositis, disseminated disease
Trachipleistophora anthropophthera	Disseminated disease, encephalitis
Tubulinosema acridophagus	Disseminated disease
Vittaforma corneae	Keratopathy, urinary tract infection, diarrhea

Epidemiology

The epidemiology of microsporidial disease is not defined clearly. Antibodies against *Encephalitozoon cuniculi* are relatively common in selected human populations, a finding suggesting that latent human infection may occur.[8]

Transmission is thought to occur from person to person and through ingestion of contaminated water and food.[4] Following ingestion, infectious spores travel to the intestine, where their contents are injected into cytoplasm of host cells. Intracellular division produces new spores that can spread to nearby cells, disseminate to other host tissues, or be passed into the environment through feces. Spores also have been detected in urine and respiratory tract epithelium, thus suggesting that related body fluids also can be infectious and that transmission also can be airborne.[4,9] Once in the environment, microsporidial spores remain infectious for up to 4 months.[9] Zoonotic transmission has been proposed, as has vector-borne transmission.[4,10] The potential for vertical transmission of infection from an infected mother has not been documented in humans, but it occurs in other mammals.[4]

Clinical Manifestations

Microsporidial infection can be caused by several different organisms and can affect multiple organ systems (see Table 268.1). *Anncaliia* species were formerly *Brachiola* species.[1–19] Corneal infections in HIV-infected patients are characterized by conjunctival irritation, photophobia, foreign body sensation, and decreased visual acuity. Slit-lamp examination reveals conjunctival hyperemia, mixed follicular-papillary tarsal conjunctival reaction, and punctate epithelial keratopathy.[9] In immunocompetent hosts, keratopathy is mainly associated with the use of contact lenses and is reported to extend deeper into the cornea than in HIV-infected patients.[16]

Microsporidia-associated diarrhea is intermittent; stools are copious, watery, and nonbloody and contain no fecal leukocytes. Clinical symptoms include crampy abdominal pain and weight loss; fever is not usually present. Because microsporidia have been found in the bile, ductal biliary cells, and gallbladder tissue of several HIV-infected patients with cholangitis, these organisms have been suggested to have a causal role in cholangitis.[11,13] Disseminated disease has been shown to involve liver, kidneys, brain, bladder, lung, bone, and sinuses.

Laboratory Findings and Diagnosis

Microsporidial infection is diagnosed by microscopic demonstration of the organism in tissue or body fluids. All microsporidia range in size from 1.5 to 5 μm in width and 2 to 7 μm in length.[6] The organism can be detected with hematoxylin and eosin, Giemsa, acid-fast, fluorescent brightening (e.g., calcofluor white, Fungi-Fluor [Polysciences, Inc., Warrington, Pa]); Gram, modified trichrome, and periodic acid–Schiff stains and with immunofluorescence assay.[4,20,21] Nonetheless, the organism can be overlooked because of its small size, variable staining, and lack of an inflammatory response. Polymerase chain reaction has been reported to be a sensitive and specific diagnostic tool.[22–25] Testing is available through the Centers for Disease Control and Prevention for *Enterocytozoon bieneusi, Encephalitozoon intestinalis, Encephalitozoon hellem,* and *Encephalitozoon cuniculi.* Identification of species can be made by electron microscopic examination, immunofluorescence, or polymerase chain reaction.[2,3,22] Current serologic tests are not helpful in diagnosis.

Treatment

Albendazole has activity against many species of microsporidia and is recommended as initial therapy.[26–31] However, albendazole is not effective against *E. bieneusi* or *Vittaforma corneae* infections. In a small, placebo-controlled trial of fumagillin (60 mg/day for 2 weeks), therapy was effective in patients with advanced HIV infection and *E. bieneusi* infection; neutropenia and thrombocytopenia were frequent adverse events.[32,33] Successful treatment of *E. bieneusi* infections also has been reported with TNP-470, a synthetic analogue of fumagillin.[33] Topical fumagillin, often in conjunction with oral albendazole, can be used to treat ocular infections.[34] Metronidazole, atovaquone, nitazoxanide, and fluoroquinolones have been reported to decrease diarrhea and other symptoms but not to eradicate the organism.[26,35–37] Topical voriconazole 1% has also been reported to be effective in cases of superficial keratitis.[38] In patients with HIV infection, immune reconstitution resulting from the initiation of effective combination antiretroviral therapy is considered the primary initial therapy, and symptoms may resolve without additional treatment.[39]

Prevention

Because transmission probably occurs by passage of infectious spores in feces, isolation precautions should be considered for hospitalized patients. Patients and caregivers should perform careful handwashing. Immunocompromised people should avoid untreated water as well as unpeeled fruits and vegetables, all of which can be contaminated.[3]

Naegleria fowleri

Joanna Nelson, Upinder Singh

Description of the Pathogen

Naegleria fowleri is a free-living ameba, and it is the only known pathogenic species of the genus *Naegleria,* which causes primary amebic meningoencephalitis (PAM) in humans and animals.[1,2] Some 30 other species have been identified according to sequencing data, some of which, like *N. australiensis* and *N. italica,* are known to cause death of experimental animals.[3,4] The organism is a facultative pathogen that occurs worldwide in soil and warm freshwater ponds, hot springs, streams, rivers, pools, and tap water. Notably, it is not found in salt water. The parasite is thermophilic and thermotolerant, proliferates in naturally and artificially warmed waters, and has an optimum activity at 37°C, but it can grow at temperatures as high as 45°C.

The life cycle includes 3 phases: trophozoite (the infective stage), flagellate, and cyst phases (Fig. 269.1). The trophozoite measures 10 to 30 µm, has a distinctive limacine (slug-like) pattern of locomotion, and has ≥1 ectoplasmic pseudopods (Fig. 269.2). *Naegleria* is the only free-living ameba that can transform into a nonreproductive, nonfeeding flagellate form in response to unfavorable environmental conditions.[5] The flagellate can in turn spontaneously revert to the trophozoite. Cysts are resistant to environmental stresses, double-walled, and approximately 9 µm in diameter, with a central nucleus and pores through which the trophozoites excyst.[5] Most remarkable feature of the molecular biology of *Naegleria* species is that the ribosomal RNA genes are carried on a 14-kb plasmid that is present as a multicopy (4000) episome.[6] The free-living *Naegleria* feed on bacteria, and unlike other pathogenic protozoa, they have no known intermediate hosts.[7]

FIGURE 269.1 Life cycle of *Naegleria fowleri. Naegleria fowleri* has 3 stages in its life cycle: (*1*) cysts, (*2*) trophozoites, and (*3*) flagellated forms. The trophozoites replicate by (*4*) promitosis (nuclear membrane remains intact). *N. fowleri* is found in freshwater, soil, thermal discharges of power plants, heated swimming pools, hydrotherapy and medicinal pools, aquariums, and sewage. Trophozoites can turn into temporary nonfeeding flagellated forms, which usually revert back to the trophozoite stage. Trophozoites infect humans or animals by (*5*) penetrating the nasal mucosa and (*6*) migrating to the brain through the olfactory nerves, thus causing primary amebic meningoencephalitis. *N. fowleri* trophozoites are found in cerebrospinal fluid and tissue, whereas flagellated forms occasionally are found in cerebrospinal fluid. Cysts are not seen in brain tissue. (From the Centers for Disease Control and Prevention DPDx. [https://www.cdc.gov/dpdx/].)

When causing human infection, amebas enter the nasal cavity, are phagocytosed by sustentacular cells of the olfactory neuroepithelium, and migrate along the unmyelinated axonal fibers of the olfactory nerve, through the cribriform plate, and into the subarachnoid space. The incubation period varies from 2 to 7 days but can be as long as 15 days after exposure. The olfactory bulbs, the base of the frontal and temporal lobes, and the cerebellum primarily are involved in a hemorrhagic, necrotizing process.[8–10]

Epidemiology

In 1965, Fowler and Carter demonstrated that free-living amebas can invade the human brain and cause rapidly fatal meningitis. Worldwide prevalence cannot be estimated reliably; however, more than 16 countries have reported cases of PAM since the 1960s.[11] In the United States from 1937 to 2007, 121 cases were reported. Most (87%) cases occurred in the summer months in the setting of recreational warm freshwater exposure; all cases occurred in southern states.[12] More than 50% of PAM cases have occurred in Florida and Texas.[11] The first reported case of PAM in Minnesota, in 2012, raised concern that ongoing climate change could contribute to a wider geographic distribution of PAM.[13] In the US, the age of patients has ranged from 8 months to 66 years, with a median age of 12 years. Among the cases where sex of the patients was documented, 78% were male.[11,12] In general, the predilection for young, healthy people may reflect behavior (e.g., more likely to remain in the water for longer periods of time, more active in the water, and more prone to diving and underwater swimming) that stirs bottom sediment that may contain amebas. In addition to freshwater, disease has been acquired through exposure to underchlorinated swimming pools.[7] Reported clusters have also been related to nasal irrigation or other exposures with infected tap water.[14–16] Similarly, examination of treated water drinking systems worldwide has also shown the presence of *Naegleria fowleri*.[17] A few cases have not followed exposure to water and were attributed to inhalation of cysts.

Clinical Manifestations

Because of the rapid progression and significant mortality rates associated with PAM, a high degree of clinical suspicion should be maintained in the setting of children and young adults presenting with acute neurologic symptoms and a history of recent freshwater exposure. The initial presentation of patients with PAM can be indistinguishable from that seen in acute bacterial or pyogenic meningoencephalitis.[18] In 94% to 100% of patients, initial symptoms of PAM consist of severe, bifrontal headaches not responsive to analgesics, fever ranging from 38°C to 41°C, pharyngitis, nasal congestion or discharge, nausea, vomiting, and altered mental status.[1,19] Some people initially notice an altered sense of smell and taste. Somnolence, confusion, signs of meningeal irritation, and convulsions are followed by coma in approximately two thirds of patients, although PAM often progresses so rapidly that focal neurologic signs do not develop. Intracranial pressure is increased terminally and commonly causes herniation of the uncus and cerebellar tonsils. The mortality rate is >95%, and death usually occurs within 3 to 10 days after the onset of symptoms.[1,20] Diffuse or focal subclinical myocarditis has been identified in approximately one half of patients at autopsy, as evidenced by neutrophils in myocardium but importantly have lacked isolation of ameba in heart tissue. In a few cases, amebas were found in extra–central nervous system tissue after death, as noted either on histologic examination or by polymerase chain reaction (PCR). Whether cross-contamination through formalin media or leakage of *Naegleria* debris over a compromised blood-brain barrier contributed to these findings is not clear, however. One report noted no transmission of PAM to 21 transplant recipients from organ donors who died of PAM.[21]

Laboratory Findings and Diagnosis

Because human naegleriasis is an acute disease, early diagnosis is essential so that appropriate antimicrobial therapy can be initiated to limit extensive amebic damage. Patients with PAM typically have leukocytosis with neutrophilia.[18] Computed tomography or magnetic resonance imaging demonstrates cerebral edema and obliteration of the subarachnoid space. Images obtained after intravenous infusion of contrast material can show marked meningeal enhancement, particularly in the basilar areas.[10,18,22]

The cerebrospinal fluid (CSF) pressure can be markedly increased (≤300–600 mm Hg), and the fluid is cloudy and slightly hemorrhagic.[18] CSF pleocytosis can be modest initially, but it increases to 400 to 26,000 cells/mm^3, with a predominance of neutrophils. The CSF glucose concentration is normal or decreased (mean, 43 mg/dL; low, 2 mg/dL), and the protein concentration usually is increased (mean, 413 mg/dL; high, 1170 mg/dL). Rapid diagnosis is made by microscopic examination, preferably using phase-contrast techniques, of freshly drawn CSF, to visualize motile amebas. Amebas can be seen on Wright- or Giemsa-stained CSF preparations. Trophozoites have a clear nucleus with a prominent, dark-staining central nucleolus that aids in distinguishing them from macrophages. The amebic cytoplasm usually contains phagocytosed material, including erythrocytes and myelin fragments. Fresh CSF preparations collected within 30 minutes of evaluation and centrifuged at slow speeds (250 times gravity) also should be examined for motile trophozoites.[1,23,24] *Naegleria* organisms are destroyed by refrigeration. Suspending amebas in 1 mL of distilled water can further confirm the identity of the amebas as *Naegleria*, by watching for the development of actively swimming flagellate forms in 1 to 2 hours.[1,25] Brain biopsy of grey matter can reveal trophozoites localized around blood vessels. Indirect immunofluorescence or immunoperoxidase staining can be used to speciate amebas in formalin-fixed, paraffin-embedded tissue sections. *Naegleria* cysts rarely are present in tissue, and identification of cysts should raise suspicion of another infective ameba, such as *Acanthamoeba* (Table 269.1).[26] CSF PCR testing has been proposed as a means of rapid diagnosis of PAM; however, PCR is not available widely.[27] Serologic tests generally are not helpful because the acutely infected patient usually dies before mounting a significant antibody response. In addition, antibody can be present in the healthy population, a finding suggesting the possibility of subclinical infection. Further corroboration can be obtained by isolation of the amebas from CSF or macerated brain tissue on a nonnutrient agar plate that has been spread with a lawn of *Escherichia coli* and incubated overnight at 37°C. The amebas grow in large numbers and feed on the bacteria. Tissue culture, especially on monkey kidney cells, also has been used to cultivate *Naegleria*.[28]

Treatment

Survival from PAM is rare, with only a few well-documented published cases. In the absence of clear guidelines, amphotericin B is the most widely accepted drug for the treatment of PAM.[29] Amphotericin B intrathecal therapy also has been used as an adjunct to intravenous amphotericin with reported success.[30,31] Amphotericin targets the parasite's plasma membrane by binding to ergosterol in the membrane, thus producing pores and causing loss of small molecules. From in vivo and in vitro evaluations, *N. fowleri* appears to be highly sensitive to amphotericin B, but delay in diagnosis and the fulminant nature of the disease result in few survivors,[32] and even with appropriate treatment selection, disease relapses have occurred.[33]

Numerous anecdotal case reports have noted success in treating *Naegleria* infections with combination therapy. These regimens have included amphotericin B in combination with rifampin or amphotericin B in combination chloramphenicol, fluconazole, or ketoconazole.[32,34–36] Miltefosine is an investigational drug now available through the Centers for Disease Control and Prevention with in vitro activity against free-living amebas.[37] One case report described a 12-year-old girl who survived after receiving miltefosine in combination with amphotericin B, fluconazole, rifampin, and azithromycin.[38] Regimens including amphotericin and azithromycin also have been suggested as possible synergistic agents in vitro and in mouse models of PAM.[39] The optimal duration of therapy is not known, but a course of at least 10 days of treatment has been used in survivors.[30,31]

Prevention

Avoidance of the free-living amebas is virtually impossible because these organisms are ubiquitous in the environment, as evidenced by the presence of antibodies in screened human populations.[40] *N. fowleri* is so common in the environment that surveillance is not indicated unless several people are infected after a common exposure.[28,41,42] The incidence of PAM is low despite populations of amebas >1 organism/25 mL of water (as found in water tested in late summer in Florida) and despite millions of exposures to recreational waters. Protective factors are unknown. *N. fowleri* is susceptible to ≤1 mg/L chlorine.[1] Proper chlorine disinfection of water in swimming pools and whirlpools and avoidance of diving and of introduction of water into the nostrils appear to be reasonable measures to avoid development of amebic encephalitis.[1] Recommendations include use of chlorine in swimming pools at 1 mg/L if the water temperature is <26°C, at least 2 mg/L if the temperature is >26°C, and 3 mg/L for temperatures >28°C.[1] Cysts are destroyed after 1 hour of exposure to pool or tap water at these concentrations.

Key Points

Epidemiology, Clinical Features, and Diagnosis of *Naegleria fowleri* Infection

Microbiology and Histopathology

- Free-living ameba

- Life cycle involves trophozoite, flagellate, and cyst forms.
- Causes hemorrhagic necrosis of central nervous system

Epidemiology

- Rare disease; 120 reported cases from 1937 to 2007 in the United States
- Exposure to warm recreational freshwater or contaminated tap water
- Primarily young, healthy people affected

Clinical Features

- Rapidly progressive fulminant meningoencephalitis
- >95% fatal

Diagnosis

- CSF findings similar to bacterial meningitis
- Microscopic identification of trophozoite in CSF

Treatment

- Therapeutic regimens are not well defined. Limited data suggests amphotericin B is the treatment of choice.

CSF, cerebrospinal fluid.

Acanthamoeba Species

Joanna Nelson, Upinder Singh

Description of Pathogen

Nearly 25 named species and 15 genotypes of *Acanthamoeba* have been identified worldwide. Previously these groups were distinguished based on morphologic features into 3 groups (I, II, III); however, molecular techniques have led to species identification based on genetic similarities.[1] *Acanthamoeba* are classified as free-living amebas because of their lack of dependence on animals to complete their life cycle. The organism has 2 phases in its life cycle: a motile trophozoite phase and a resilient infective cyst stage (Fig. 270.1). Trophozoites are 25 to 50 μm in diameter and have distinctive slender, spine-like projections of the plasma membrane called acanthopodia (Fig. 270.2). The cysts have a double-layered wall and are 15 to 30 μm in diameter. Both forms have a wide distribution in nature. Several species of *Acanthamoeba* are known pathogens in humans. *A. castellanii, A. culbertsoni, A. polyphagia, A. astronyxis, A. palestinensis, A. healyi*, and *A. divionensis* usually cause fatal, subacute disseminated disease with granulomatous amebic encephalitis in immunocompromised hosts.[2,3] Additionally, *A. polyphagia, A. castellanii, A. culbertsoni, A. hatchetti, A. rhysodes, A. quina, A. lugdunensis*, and *A. griffini* can cause amebic keratitis, a vision-threatening disorder predominantly seen in immunocompetent contact lens wearers.[2]

Epidemiology

Acanthamoeba species have been isolated readily from water (including treated water; brackish water; seawater; swimming pools; sewage; domestic tap water; bottled mineral water; cooling, heating, and humidifying units; hot tubs; hospitals and dialysis units; dental irrigation units; eyewash stations; and contact lenses and associated paraphernalia), soil, dust, air, and sediments and as contaminants in cell cultures.[2–4] Limited seroprevalence surveys of healthy people have demonstrated antibodies from immunoglobulin M (IgM) and IgG classes to *Acanthamoeba* species, a finding indicating that asymptomatic infections likely occur.[5,6] People with compromised immune systems such as those with diabetes mellitus, chronic liver disease, renal failure, or systemic lupus erythematosus, transplant recipients, patients receiving chemotherapy or corticosteroids on a longterm basis, pregnant women, and human immunodeficiency virus (HIV)–infected people are at risk for severe manifestations of *Acanthamoeba* infections such as disseminated disease and granulomatous amebic encephalitis.[7–13] Difficulties in diagnosing amebic encephalitis limits the ability to capture the true incidence of disease. Although central nervous system (CNS) disease with *Acanthamoeba* occurs predominantly in immunocompromised people, cases have been reported in both adults and children with intact immune systems.[14–22]

Amebic keratitis most commonly occurs in immunocompetent contact lens wearers, but it can also be related to corneal trauma. In a multicenter review of 116 cases in the United States, 96% of cases were associated with contact lens use.[23] The estimated annual incidence ranges from 1.7 to 19.5 cases per 1,000,000 contact lens wearers.[24] Previous outbreaks were related to the use of nonsterile, homemade saline solution in the 1980s and the use of a specific contact lens solution in 2007 that was later recalled.[25,26] Poor lens hygiene, water contamination, and ineffectiveness of disinfectant solutions against *Acanthamoeba* likely play roles in ongoing infections.[24,25,27]

Clinical Manifestations

Acanthamebic encephalitis usually is termed *granulomatous amebic encephalitis* because of its pathologic appearance. The disease generally occurs after infection at other sites, thus implying that trophozoites reach the CNS by hematogenous dissemination.[8] The route of infection is thought to be by inhalation of amebae through the nasal passages and lungs or introduction through skin lesions. Although the incubation period for *Acanthamoeba* infections is unknown, it can be several weeks or months. The neurologic symptoms of granulomatous amebic encephalitis have an insidious onset and include focal deficits such as hemiparesis, diplopia, cranial nerve palsies (especially of cranial nerves III and VI), and cerebellar ataxia. Nonfocal neurologic manifestations include personality changes, seizures, headache, meningismus, nausea, stiff neck, lethargy, altered mental status, signs of increased intracranial pressure, and coma.[28] Low-grade intermittent fever, nausea, and vomiting also can occur. The disease usually is fatal after an average of 39 days of illness (range, 7–120 days).

The symptoms of *Acanthamoeba* keratitis often begin with the sensation of a foreign body in the eye, followed by severe (usually unilateral) ocular pain, redness, photophobia, tearing, blurred vision, and eyelid edema. Clinical findings during early disease (within the first 4 weeks) are characterized as epitheliopathy, with perineural infiltrates pathognomonic. Late disease (after 4 weeks) is characterized by ring infiltrates, ulceration, and secondary sterile anterior uveitis, sometimes with hypopyon (Fig. 270.3). Limbitis can be seen in both early and late disease. Waxing and waning of symptoms and physical signs are common and often result in delayed diagnosis, and bacterial superinfection is not uncommon.[24] Blindness can result if disease progresses without treatment. In rare circumstances, *Acanthamoeba* can spread from the cornea to the retina, thereby causing chorioretinitis. On these occasions, the spread of *Acanthamoeba* has been postulated to have been facilitated by combined keratoplasty, extracapsular cataract extraction, and intraocular lens insertion.[29]

Cutaneous infections often are a reflection of disseminated disease caused by *Acanthamoeba* and are most common in patients with acquired immunodeficiency syndrome (AIDS), but they can also be seen in other immunosuppressed patients such as organ transplant recipients or patients with malignant disease who are receiving chemotherapy.[30–34] The cutaneous form of the disease is characterized by the presence of hard erythematous nodules or skin ulcers.[35] Early manifestations include the presence of firm papulonodules that become abscesses, drain purulent material, and then develop into nonhealing, indurated ulcerations.[2,36,37] The mortality rate in patients with cutaneous infection in patients without CNS involvement is approximately 73%, whereas the mortality rate in patients with cutaneous infection accompanied by CNS disease is 100%.[30] Other manifestations of *Acanthamoeba* infections in HIV-infected patients include sinus infection, which manifests with the typical symptoms of sinusitis.[38]

Laboratory Findings and Diagnosis

The diagnosis of granulomatous amebic encephalitis depends on isolation or histologic demonstration of *Acanthamoeba* from a brain biopsy specimen (see Fig. 270.2). Various stains (e.g., hematoxylin and eosin, Wright, Giemsa, periodic acid–Schiff, and calcofluor white) highlight the trophozoites or cysts in tissue, which in the brain often localize to the perivascular spaces. Indirect immunofluorescent and immunoperoxidase staining methods can be used to confirm the diagnosis. Polymerase chain reaction of brain tissue can also aid in the diagnosis.[39] Computed tomography of the head has shown mass lesions that resemble abscesses, tumors, or hemorrhage.[2,40] These lesions often are multifocal and occasionally nonenhancing and occur throughout the cortex, brainstem, and spinal cord. Lumbar puncture can be contraindicated because of these space-occupying lesions, but when it is performed, the cerebrospinal fluid (CSF) has elevated opening pressure, lymphocytic pleocytosis, moderately elevated protein concentrations, and low glucose concentrations. Although the CSF traditionally has been considered sterile, reports have noted motile trophozoites and positive culture results from CSF samples from children.[14,21] Culture requires that tissue be inoculated onto nonnutrient agar overlaid with *Escherichia coli* or *Enterobacter aerogenes,* which serve as food sources for the ameba.[26,41] The organism also can be isolated from culture of skin lesion swabs, and in suspected cases biopsy should be performed on skin lesions.

In vivo confocal microscopy for the diagnosis of amebic keratitis has emerged as a useful noninvasive diagnostic tool, with sensitivity and specificity reported at greater than 90%, although these numbers can be operator dependent.[25,28] A suspected diagnosis based on this technique should then be confirmed by isolation or demonstration of *Acanthamoeba* in corneal scrapings or corneal biopsy specimens by culture or histopathologic examination. Scrapings should be examined for motile trophozoites or cysts as a wet mount before drying or fixation. Polymerase chain reaction can be used for diagnosis and has a specificity of 84% compared with 53% for culture in 1 study.[42] Staphylococci, streptococci, and other bacteria have been isolated concurrently in some cases and can confound the diagnosis. *Acanthamoeba* has also been isolated from contact lenses, lens cases, lens-cleaning solutions, and corneal tissues.[26]

Treatment

Central Nervous System Infections

Treatment of granulomatous amebic encephalitis rarely is successful, probably because of a combination of late diagnosis and antimicrobial failure. Although no standard regimen exists, anecdotally successful regimens have involved combination therapy including pentamidine, sulfadiazine, trimethoprim-sulfamethoxazole, flucytosine, and fluconazole, ketoconazole, or itraconazole.[3,43] Treatment of granulomatous amebic encephalitis in immunocompromised hosts can be particularly challenging; however, treatment success has been reported with combination therapy using fluconazole, pyrimethamine, and sulfadiazine along with surgical resection of the CNS lesion.[44] Oral regimens including a combination of trimethoprim-sulfamethoxazole, rifampin, and ketoconazole have been used successfully to treat children with chronic *Acanthamoeba* meningitis.[14] A small retrospective analysis suggested that adding miltefosine to treatment regimen may increase survival, but more data are needed to make definitive conclusions.[45] Miltefosine is currently available through the Centers for Disease Control and Prevention as an investigational drug to treat free-living ameba infections.

Cutaneous Disease

Patients with cutaneous acanthamebiasis have been treated with various drugs. Successful treatment of a patient with AIDS with cutaneous and sinus lesions by using 40 mg/kg of 5-fluorocytosine orally for 2 weeks was reported.[46] Topical therapy with miltefosine also is a consideration in the immunocompromised host.[47] Some treatment regimens that can be successful in 1 patient can yield a poor outcome in another. For instance, intravenous pentamidine in combination with topical chlorhexidine and 2% ketoconazole cream, followed by itraconazole orally, has been used successfully,[48] although failure of a similar regimen was reported in another patient.[49] *Acanthamoeba* isolates have shown varied susceptibility patterns among species and among strains of the same species; thus susceptibility testing is recommended to guide therapy.[50]

Keratitis

Treatment of amebic keratitis can be effective, particularly when therapy is initiated early. Treatment entails use of topical antiamebic agents and, in more severe cases, surgical debridement. No clear guidelines are available for treatment of this disease; however, combination therapy with either topical chlorhexidine or polyhexamethylen biguanide (PHMB), plus dibromopropamidine, are commonly used successfully.[2,26] Adjunctive oral and topical therapies such as ketoconazole and itraconazole can be considered.[25] The use of adjunctive topical corticosteroids is controversial. Although some reports of corticosteroid therapy controlling inflammation, pain, and ulceration exist,[51] the use of these drugs has been complicated by crystalline keratopathy caused by infection with viridans streptococci (including *Streptococcus oralis*) and *Staphylococcus aureus.*[52] When medical therapy with debridement has failed, penetrating keratoplasty, corneal transplantation, and even enucleation have been required.[26]

Prevention

The ubiquitous nature of *Acanthamoeba* argues against complete prevention of granulomatous amebic encephalitis in highly immunocompromised people. *Acanthamoeba* keratitis, however, is largely a preventable disease if proper contact lens care techniques are followed and swimming with contact lenses is avoided. Additional appropriate prevention measures include thermal disinfection of contact lenses, use of hydrogen peroxide–containing solutions (2-step processes are better than 1-step), good lens case care, and the use of an amebicidal storage solution (a combination of PHMB and chlorhexidine appears to be ideal).[53,54] Sterile saline containing benzalkonium preservatives (chlorine-based solutions are not effective against *Acanthamoeba*) should be used for lens storage.

Key Points

Epidemiology, Clinical Features, and Diagnosis of *Acanthamoeba* Infection

Microbiology and Histopathology

- Free-living ameba with 2 stages: trophozoite and cyst
- Trophozoite has characteristic acanthopodia: spine-like projections of plasma membrane.
- Brain biopsy shows edema, multinucleated giant cells, hemorrhagic necrosis; both cysts and trophozoites can be found in tissue.

Epidemiology

- Found ubiquitously in water and soil
- Causes disseminated disease and granulomatous amebic encephalitis in immunocompromised patients
- Amebic keratitis most common in contact lens wearers

Clinical Features

- Granulomatous amebic encephalitis manifests as insidious onset of focal neurologic deficits, personality changes, altered mental status, fever, progressing to seizure, increased intracranial pressure, coma, and death.
- Cutaneous lesions are firm papulonodules that become abscesses, drain purulent material, and then develop into nonhealing indurated ulcerations.
- Keratitis manifests with foreign body sensation, ocular pain, and

redness.

Diagnosis

- Biopsy of affected tissue for culture, histopathologic examination, immunohistochemical staining, or polymerase chain reaction

Treatment

- Therapeutic regimens are not well defined; surgical debridement may play an adjunctive role.

Plasmodium Species (Malaria)

Julie Gutman, Paul M. Arguin

Although malaria is a major cause of morbidity and mortality in the world, most cases in the United States and Europe occur in people who have traveled to or emigrated from endemic areas.[1] Obtaining a travel history from all patients who present with fever and having a high index of suspicion for malaria in people who have recently traveled to a malaria-endemic area are important because infection can be rapidly fatal. In addition, malaria rarely is acquired from blood transfusion, through congenital transmission, or through transmission from an imported case. This chapter focuses on malaria as it is likely to be encountered in nonendemic settings.

Description of the Pathogen

Five species of malarial parasites can naturally infect humans. Humans are the natural hosts for 4: *Plasmodium falciparum, P. vivax, P. ovale,* and *P. malariae,* whereas the fifth, *P. knowlesi,* typically infects macaques. Although all species of malaria can cause severe infections, *P. falciparum* is the most lethal and the most drug resistant. Of the human species, *P. vivax* was previously the most widely distributed geographically and the best adapted to survive in temperate climates. However, successful malaria control programs in the US and Europe essentially eliminated *P. vivax* from these regions. *P. falciparum* is the most prevalent species in sub-Saharan Africa. *P. ovale* mainly occurs in the western areas of sub-Saharan Africa. *P. knowlesi* normally infects macaques in Southeast Asia; however, it has been implicated in human cases throughout Southeast Asia and is responsible for approximately 50% of cases in Malaysia. Different stages of *P. knowlesi* closely resemble *P. malariae,* thus making it difficult to diagnose by microscopy. In contrast to the usually benign infections with *P. malariae,* infection with *P. knowlesi* can be rapidly fatal, so considering this possibility when treating patients who could have acquired malaria in this region is important, to minimize severe morbidity and mortality.[2]

The life cycles of all human malarial parasites are illustrated in Fig. 271.1. Sporozoites are inoculated into humans by the bite of an *Anopheles* species mosquito and invade hepatic parenchymal cells within minutes. The parasites undergo asexual multiplication, or schizogony, in this tissue phase of their life cycle, also called exoerythrocytic schizogony. After a period of development and multiplication (7–10 days for *P. falciparum, P. ovale,* and *P. vivax* and 10–14 days for *P. malariae* and *P. knowlesi*), merozoites emerge to invade erythrocytes and begin what will become the symptomatic phase of the illness. Parasites of the 2 relapsing species, *P. ovale* and *P. vivax,* also can differentiate into a quiescent stage, the hypnozoite, which later can enter into schizogony and reemerge to invade erythrocytes. *P. malariae* has the potential to persist at very low levels in the circulation for decades if it is not recognized and treated.

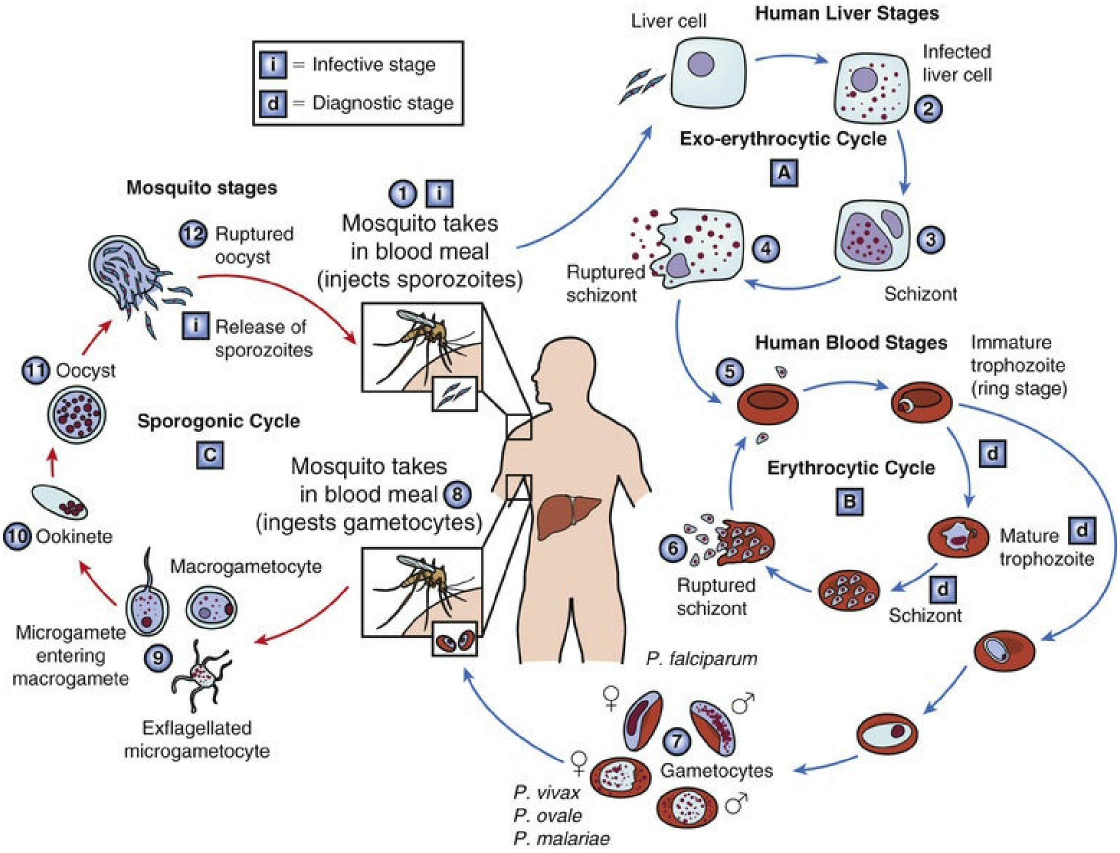

FIGURE 271.1 Generalized life cycle of malarial parasites in the anopheline mosquito vector and in humans. **(From the Centers for Disease Control and Prevention.)**

Each species has developed an efficient strategy for erythrocyte invasion that relies on a specific, complex interaction of certain surface proteins or glycoproteins on the erythrocyte and a specific ligand of the parasite. For example, *P. vivax* preferentially invades erythrocytes bearing the Duffy blood group antigen, an antigen that is rarely found on erythrocytes in people from West and central Africa[3]; consequently *P. vivax* malaria is uncommon throughout most of West Africa. *P. falciparum* invades erythrocytes of all ages, while *P. vivax* and *P. ovale* preferentially invade reticulocytes, and *P. malariae* and *P. knowlesi* preferentially invade mature erythrocytes. Once inside the erythrocyte, parasites can undergo either asexual schizogony or sexual differentiation to produce gametocytes.

During asexual schizogony, the parasites are known as trophozoites once they are established inside the erythrocyte; the early trophozoite forms often are called rings because of their apparent lack of central cytoplasmic staining. Parasites in this stage ferment homolactate and actively digest the host cell hemoglobin, which they use as a source of amino acids and energy.[4] This activity is accomplished through a set of highly adapted proteinases in a singularly adapted organelle, the food vacuole.[5] The residue of hemoglobin degradation is an intact tetrapyrrole ring, ferriprotoporphyrin IX, which the parasites detoxify through polymerization and can be seen microscopically as malarial pigment, hemozoin.[6] This polymerization step is thought to be the site of action of quinoline-containing antimalarial compounds, including chloroquine.[7,8]

The actual replicative phase, when the parasite is called a schizont, comprises the last few hours of the erythrocytic stage of the parasite's life cycle, during which the parasite undergoes mitosis and subdivides and differentiates into merozoites. The subsequent rupture and release of merozoites lead to fever and other malarial symptoms. In synchronized infections, which typically occur only after the infection is well established, the periodicity of symptoms is 48 hours in *P. ovale* and *P. vivax* malaria, 72 hours in *P. malariae* infections, and 24 hours in *P. knowlesi* infections.[9] Although periodicity can be every 48 hours in *P. falciparum* infections, it often is irregular. The absence of periodicity does not rule out malaria (any species) as a diagnosis for a febrile illness in a person with an appropriate travel history.

Parasites in the erythrocytic stages also can undergo sexual differentiation, a step that is necessary for transmission. Male and female gametocytes, which are produced by each *Plasmodium* species, remain inside the erythrocyte until they are ingested by the mosquito. At this point, they undergo further differentiation and join to form a zygote, which differentiates into an ookinete and invades the mosquito midgut to form the reproductive oocyst. Sporozoites emerge from the oocyst and migrate to the salivary gland, where they can reinfect a human during a subsequent blood meal.

In general, all the erythrocytic asexual and sexual developmental stages of *P. ovale, P. vivax, P. malariae,* and *P. knowlesi* occur in circulating blood and can be visualized in the peripheral blood smear. The late trophozoite stages of *P. falciparum* rarely are seen in the peripheral circulation because of the development of “knobs” on infected erythrocytes that lead to adherence of the parasitized erythrocytes to the capillary endothelium.[10] Sequestration of parasites in various organs is believed to be responsible for the clinical manifestations of *P. falciparum* infections, such as central nervous system and pulmonary complications.

No strict immunity per se develops to malaria, but rather an acquired ability to tolerate *Plasmodium* spp. infections occurs that is a selective process related to the degree of exposure to a variety of strains.[11] Most deaths caused by malaria in malaria-endemic areas with high transmission of *P. falciparum* occur in children <5 years of age. Although *P. falciparum* can cause lethal infection in young children or nonimmune people, asymptomatic parasitemia is common in older age groups in highly endemic areas. In the US, most malaria cases occur among first- and second-generation immigrants returning to their countries of origin to visit friends and relatives and who either do not believe that malaria prophylaxis is necessary or are unaware of the need to take prophylaxis while traveling, despite their loss of immunity.[1] Malaria deaths in the US occur among all age groups.

Epidemiology

The epidemiology of malarial infections is intricately linked to the distribution and habits of the anopheline vectors in any particular region. In highly endemic areas, mosquito breeding can take place nearly year round, and reproductive capacity in the mosquito is maximized by a tropical climate.[12] In areas of seasonal transmission, prevalence is particularly related to rainfall or other ecologic events that affect the mosquito population. Malaria also can be related to occupation when only certain segments of the population are exposed to the vectors (e.g., in places where cases occur in men whose jobs require them to enter the forests where the vectors live). In nonendemic countries such as the US, the epidemiology of malaria is most closely linked to international travel patterns.

The estimated worldwide incidence of malaria is 212 million (uncertainty range, 148 million to 304 million) clinical malaria episodes per year, with an estimated 429,000 deaths (uncertainty range, 235,000 to 639,000) in 2015, most of which occurred in children <5 years of age.[13] Almost all deaths are caused by *P. falciparum*, with more than 80% occurring in sub-Saharan Africa. Before the 1950s, malaria was endemic in the US. During the late 1940s, a combination of improved housing and socioeconomic conditions, water management, vector-control efforts, and case management was successful in interrupting malaria transmission. In the US today, an average of 1500 cases and 5 deaths occur each year; almost all cases are in people who have traveled to or are emigrating from malarious areas,[1] although transmission occasionally occurs congenitally or through transfusion or transplantation. From 1963 to 2012, 97 cases of malaria acquired through transfusion were reported in the US.[14] From 1966 to 2005, 81 cases of congenital malaria were reported in the US.[15] Anopheline vectors still are present in most areas of the US, and, infrequently, localized instances of malaria have occurred because of transmission from imported human cases.[16]

Clinical Manifestations

The clinical features of malaria depend on the malaria-specific immune status of the host and the infecting species of *Plasmodium.* Nonimmune people (e.g., those who have not resided in an endemic area or have moved away from an endemic area) generally develop symptomatic illness. Infections with *P. falciparum* are more likely to become severe than are infections with the other 4 species that naturally infect humans.

The febrile paroxysm is the hallmark of malaria and typically lasts from 10 to 12 hours. It consists of a period of intense rigors or chills, followed by high fever that can induce a febrile seizure; profuse sweating occurs with defervescence. Other nonspecific symptoms at the time of fever include headache, malaise, myalgia, and arthralgia. Gastrointestinal tract symptoms, including abdominal pain, vomiting, and diarrhea, can occur. Although prostrated during febrile episodes, people otherwise can be remarkably asymptomatic between episodes.

Given the variable and nonspecific clinical findings and the potential for rapidly fatal disease, a high index of suspicion for malaria is necessary in ill travelers who have returned from an endemic area. Another complicating factor is that nonimmune people can have clinical symptoms despite low levels of parasitemia. Thus 3 thick and thin blood smears separated by 12 to 24 hours are recommended to exclude a diagnosis of malaria.

Significant morbidity and mortality rates from *P. falciparum* infections result from cerebral effects.[17] Delirium and confusion can occur with the high fever of malaria, but declining mental status is more ominous and indicates the need for urgent treatment. Symptoms can progress rapidly to coma. Whereas meningismus, generalized seizures, and symmetric upper motor neuron dysfunction can be seen, focal seizures or localizing neurologic signs are uncommon in malaria. The rapid recovery of central nervous system function with antimalarial treatment and the general lack of sequelae suggest metabolic encephalopathy as the probable mechanism of dysfunction. The highest risk for neurologic sequelae is in patients with multiple seizures, prolonged coma, hypoglycemia, and clinical features of intracranial hypertension.[18,19]

The combination of respiratory compromise and renal dysfunction with *P. falciparum* infection also is associated with increased mortality rates.[20] Respiratory distress syndrome can occur after initiation of appropriate therapy with clearance of parasitemia and should not be considered a failure of therapy. Renal dysfunction most commonly occurs as acute tubular necrosis, probably secondary to hypoperfusion from hypotension or hypovolemia. Although reported in children, this complication is observed more frequently in nonimmune adults. Nephrotic syndrome and glomerulonephritis have been associated with chronic infections with *P. malariae* in children, but these findings are not common.

Hyperparasitemia (≥5% red blood cells [RBCs] infected) is an independent marker of severe disease. It occurs with *P. falciparum* infection in nonimmune people and frequently is associated with hypotension, metabolic acidosis, and hypoglycemia.[17,20] These signs all can be attributed to parasitemia and associated cytokine disturbances, although concomitant gram-negative bacillary septicemia has been reported, particularly in association with severe gastrointestinal tract symptoms.[20] Hypoglycemia must be managed aggressively and monitored carefully, particularly during quinine or quinidine therapy.

Anemia is an expected consequence of malaria, especially in patients with hyperparasitemia. Hemolysis from erythrocytic parasitosis, sequestration and RBC destruction resulting in hypersplenism, and dyserythropoiesis have been identified as mechanisms contributing to anemia.[21] Thrombocytopenia is extremely common in malaria, including very low platelet counts, but it rarely leads to bleeding diathesis. Evidence of consumptive coagulopathy is rare but can occur with *P. falciparum* infection in nonimmune people, and it usually develops in the setting of “algid” malaria, a septic shock–like syndrome. Brisk hemolysis with hemoglobinuria, called blackwater fever, can occur with hyperparasitemia in nonimmune people. However, this condition is more common as an epiphenomenon in people residing in endemic areas and is associated with prolonged quinine intake (which is no longer recommended) or in glucose-6-phosphate dehydrogenase (G6PD)–deficient people who are using oxidant antimalarial drugs.

Although complications of malaria are generally limited to the acute illness, prolonged convalescence is common. In general, full recovery from any pulmonary, renal, or central nervous system compromise is the rule. The exception occurs in children with cerebral malaria, up to 10% of whom may have residual neurologic deficits.[19]

Laboratory Findings and Diagnosis

The most important step in making the diagnosis of malaria is including it in the differential diagnosis. Many of the deaths caused by malaria in the US are related to a delay in diagnosis.[22] Malaria should be considered the primary diagnosis until proven otherwise in any febrile patient who has traveled to or emigrated from an endemic area. Malaria also should be considered in patients who develop fever within days to a few months after blood transfusion.

The diagnosis of malaria is made by identifying parasites in thick or thin blood films stained with common hematologic stains, most typically Giemsa-based stains. The thick film preparation is the more sensitive technique, but it is more difficult to interpret by inexperienced examiners. Speciation and quantification are performed with a thin smear. For initial clinical management, identifying the presence or absence of malaria parasites is most important. If the parasites are present, determining the percentage of parasitemia is essential for management because patients with ≥5% infected RBCs have a greater incidence of complications and require immediate therapy intravenously. To quantify malaria parasites, between 500 and 2000 RBCs should be examined.

Erythrocytes infected with multiple parasites are counted as a single infected RBC. Gametocytes should not be counted in the evaluation of parasitemia (Fig. 271.2).

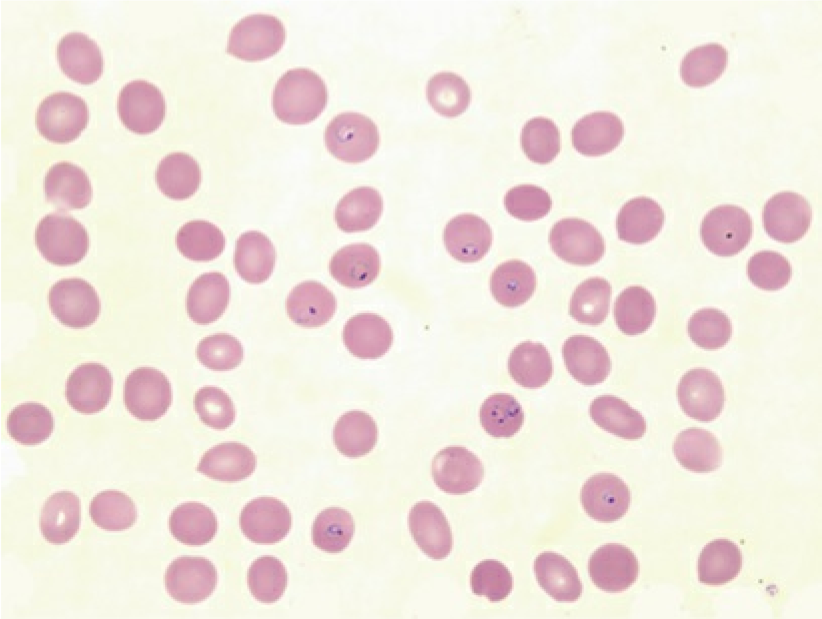

FIGURE 271.2 Calculation of parasitemia on a thin blood film. This image shows 59 red blood cells. Eight of the red blood cells have malaria parasites. Note that 1 of the red blood cells has 2 parasites. For the purposes of parasitemia calculation, this counts as 1 infected red blood cell. Between 500 and 2000 red blood cells should be counted, thus requiring the viewing of multiple fields. Parasitemia is the number of infected red blood cells divided by the total number of red blood cells counted.

P. falciparum is strongly suggested by RBC parasitemia >2%, RBCs containing multiple parasites, the exclusive presence of ring forms, and a lack of schizonts. *P. falciparum* is identified pathognomonically by the banana-shaped gametocyte form; the presence of this form is helpful, but its absence does not exclude the diagnosis. Late trophozoite stages of *P. falciparum* rarely are seen except in the setting of high-level parasitemia. A quantitative assessment of the initial parasitemia also is useful in assessing the patient's response to therapy.

Various test kits are available to detect antigens derived from malaria parasites. Such tests most often use a dipstick or cassette format, and they provide results in 15 to 20 minutes. These rapid diagnostic tests (RDTs) offer useful alternatives to microscopic examination when reliable microscopic diagnosis is not available. One RDT for malaria (Binax NOW Malaria, Alere, Waltham, Mass) was approved for use by the US Food and Drug Administration (FDA) in 2007. This RDT detects the histidine-rich protein 2 (HRP2) of *P. falciparum* malaria, as well as a panmalarial aldolase produced by all malaria species. The sensitivity of this test to detect *P. falciparum* malaria is reported to be 95%, whereas the sensitivity for *P. vivax* is only approximately 69%.[23] Sensitivity is lower in patients with low-level parasitemia (<200 parasites/mm^3). World Health Organization product testing of Binax NOW detected 91% of *P. falciparum* isolates at 200 parasites/mm^3 but only 10% of *P. vivax* isolates at 200 parasites/mm^3.[24] Although RDTs can be useful in making a rapid diagnosis, all Binax NOW tests, whether results are negative or positive, must be followed by microscopic evaluation of a blood smear.

Parasite nucleic acids can be amplified and detected by polymerase chain reaction, which can be a useful complement to microscopic examination. It is now recommended that all cases of malaria diagnosed in the US undergo species confirmation by polymerase chain reaction.[25] In addition, the Centers for Disease Control and Prevention (CDC) conduct surveillance for drug resistance mutations for malaria cases diagnosed in the US. By so doing, emerging resistance patterns in endemic countries can be detected more rapidly, thus leading to improved treatment strategies in those endemic countries as well as improvements in prevention guidelines for travelers. All laboratories in the US that diagnose malaria are encouraged to send blood samples from all cases to the CDC for surveillance. Testing is free of charge, and details can be found on the CDC website.[26] Currently, polymerase chain reaction is not sufficiently widely available with a rapid enough turnaround time to make it a viable choice for primary malaria diagnosis.

Serologic testing (immunofluorescence assay) detects antibodies against malaria parasites. Because of the time required for development of antibody and also the persistence of antibodies, however, serologic testing is not useful for routine diagnosis of acute malaria infection or illness.

Although no other laboratory findings are diagnostic for malaria, several laboratory findings support the diagnosis and can be useful to assess the severity of infection. Generally, patients have normocytic, hemolytic anemia with a variable white blood cell count and differential count. Thrombocytopenia often is present, and platelet counts are frequently lower than 50,000/mm^3. In the setting of cerebral malaria, when meningitis also must be excluded, lumbar puncture can reveal raised opening pressure, and cerebrospinal fluid analysis can show mildly elevated protein level and mild lymphocytic pleocytosis. Electrolyte disturbances, including acidosis and mild hyponatremia, are common in severe malaria and usually are multifactorial in origin, including dehydration, vomiting, renal failure, and tissue hypoxia. Hypoglycemia can occur and can be exacerbated by treatment with quinidine. Urinalysis results generally are normal except for proteinuria during high fever. Urinalysis also can reveal hemoglobinuria in the setting of brisk hemolysis, proteinuria associated with nephrotic syndrome, or RBCs with glomerulonephritis. Mildly elevated serum hepatic transaminase levels and indirect hyperbilirubinemia can be present; hepatic failure is uncommon and should prompt evaluation for other causes.

Treatment

Once the diagnosis of malaria is made, multiple factors must be assessed to establish an appropriate strategy for treatment. The first factor to consider is whether the patient has uncomplicated or severe malaria (Box 271.1). Other factors that affect therapy are the likelihood of antimalarial drug resistance (usually based on the geographic region in which malaria was acquired) and the use of antimalarial chemoprophylaxis[27,28] (see also Chapter 296).

Box 271.1

Manifestations of Severe Malaria

Cerebral malaria, defined as unarousable coma not attributable to any other cause in a patient with *Plasmodium falciparum* malaria

Seizures

Severe normocytic anemia with hematocrit <15%

Hypoglycemia

Metabolic acidosis with respiratory distress

Fluid and electrolyte disturbances

Acute kidney injury

Acute respiratory distress syndrome

Hypotension, shock, septicemia (“algid malaria”)

Abnormal coagulation

Hemoglobinuria

Hyperparasitemia (>5% of red blood cells infected)

Patients with *P. falciparum* malaria and those in whom *P. falciparum* cannot be excluded because the species has not been determined at the time of diagnosis should be hospitalized for therapy and monitored because of the rapid clinical deterioration that can occur even if the patient initially appears stable (see Box 272.1). Therapy should be started immediately and supportive care given as necessary. If the patient has severe malaria or is unable to tolerate oral therapy, intravenous quinidine in combination with doxycycline, tetracycline, or clindamycin should be used in a setting in which cardiovascular status and hypoglycemia can be monitored closely and managed urgently (Table 271.1, Box 271.2).[29] As newer antiarrhythmic drugs have replaced quinidine for many cardiac indications, some hospitals and other healthcare facilities have dropped quinidine gluconate from their formularies. Clinicians providing care for patients with malaria should be aware of the inpatient availability of quinidine to avoid delays in treatment.

Management of Patients With Severe Malaria

Hospitalize the patient.

Initiate intravenous antimalarial therapy immediately.

Correct fluid balance and electrolyte abnormalities cautiously.

Monitor, prevent, and correct hypoglycemia.

Correct anemia as needed.

Provide antipyretic therapy.

Protect the airway in patients with altered mental status.

Avoid harmful adjuvant therapies.

Patients with severe malaria should be given an intravenous loading dose of quinidine unless they have received >40 mg/kg of quinine in the preceding 48 hours or if they have received mefloquine within the preceding 12 hours. Consultation with a cardiologist and a physician with experience in treating malaria is advised when using quinidine to treat patients with malaria. An electrocardiogram should be performed before initiation of quinidine therapy to determine a baseline QTc interval. During administration of quinidine, monitoring of blood pressure (for hypotension) and continuous cardiac monitoring (for widening of the QRS complex or lengthening of the QTc interval) are required, and blood glucose concentrations should be evaluated (for hypoglycemia) periodically.[29] Cardiac complications, if serious, may warrant temporary discontinuation of the drug or slowing of the intravenous infusion. Exchange transfusion is no longer recommended by the CDC. Although exchange transfusion can rapidly reduce parasitemia, decades of use have not demonstrated an impact on survival.[30]

Clinical deterioration can occur in the first 24 hours despite appropriate therapy, particularly in patients with high-level parasitemia. Supportive care during this period is critical and should include careful monitoring for hypoglycemia and anemia, careful management of fluid and electrolyte disturbances, monitoring for respiratory and renal compromise, and protection of the patient's airway if declining mental status is evident. Adjunctive therapies such as corticosteroids, heparin, epinephrine, desferrioxamine, cyclosporine, prostacyclin, or osmotic agents for cerebral edema have not proven effective for severe malaria, and considerable evidence suggests potential harm from some of these treatments.

When intravenous quinidine is unavailable, contraindicated, or not tolerated, intravenous artesunate, an investigational drug available through the CDC, can be provided. Artesunate is not FDA approved but has been accepted widely for the treatment of malaria in other countries.[31–33] The CDC should be contacted through the Malaria Hotline (770-488-7788 during working hours; 770-488-7100 after hours and weekends) for any cases for which use of this investigational drug can be indicated. Parenteral artesunate has been associated in rare cases with delayed hemolysis, which occurs 1 to 3 weeks after initiation of treatment with artemisinin-based antimalarial agents, primarily among European travelers who received intravenous artesunate. The phenomenon is thought to be the result of delayed clearance of previously infected erythrocytes, which continue to circulate after the parenteral artesunate has been cleared, rather than a toxic effect of the drug.[34] Although the hemolysis can cause a significant drop in hemoglobin (median reduction, 6 g/dL), no associated fatalities have been reported.[35] Parasitemia should decrease substantially after the first 48 hours of effective antimalarial therapy. Parasites generally clear by 72 hours, and the persistence of parasites should prompt evaluation of possible causes, including inadequate dosage or possible drug resistance. Gametocytes of *Plasmodium* spp. are not killed by most therapies and can be seen for weeks after the initiation of treatment; this finding should not be considered a sign of drug failure, and no additional antimalarial therapy is required. Gametocytes should not be counted in the evaluation of parasitemia level.

Oral chloroquine can be used in patients with uncomplicated malaria caused by *P. falciparum* if infection was acquired in parts of the world free of widespread chloroquine resistance (see http://www.cdc.gov/malaria/travelers/country_table/a.html) and if the patient is able to take oral medication (see Table 271.1). Patients with *P. falciparum* malaria acquired in all other geographic areas should be treated with artemether-lumefantrine (Coartem), atovaquone-proguanil (Malarone), mefloquine, or with a combination of oral quinine sulfate *plus* tetracycline, doxycycline, or clindamycin. Because of the ease of dosing and low rates of side effects, artemether-lumefantrine or atovaquone-proguanil may be preferred, but all 4 options should be considered equally effective. Beginning an effective antimalarial medicine as soon as possible is of paramount importance. For patients with *P. falciparum* acquired in border areas of Southeast Asia, treatment with quinine should be continued for 7 days (instead of 3–7 days) because of evidence of declining efficacy. Doxycycline, tetracycline, or clindamycin should not be used alone for malaria therapy because of the delayed onset (48 hours) of action of these drugs. Mefloquine should not be used in patients who have acquired infection in Southeast Asia because of the high levels of resistance, nor should this drug be used in patients with a history of psychiatric illness.

Patients who do not have *P. falciparum* infection and who have no signs of severe disease can be treated with chloroquine or hydroxychloroquine (Plaquenil) as outpatients, depending on their overall clinical status, and if they are monitored for symptomatic improvement (see Table 271.1). Chloroquine treatment failure rates are high among patients with *P. vivax* infections acquired in Papua New Guinea and Indonesia, and thus patients with *P. vivax* infections acquired in these areas should not be treated with chloroquine or hydroxychloroquine.[36] If the patient cannot take oral medication, intravenous quinidine is the drug of choice. If the patient does not respond to treatment with chloroquine, the treatment should be changed to a regimen effective against chloroquine-resistant *P. vivax;* any regimen effective against chloroquine-resistant *P. falciparum* is suitable.

If the infecting species is identified as *P. vivax* or *P. ovale,* treatment with primaquine also is necessary to prevent relapse from latent hypnozoite forms in the liver (see Table 271.1). G6PD deficiency must be excluded before primaquine is administered. Ideally, primaquine therapy should be initiated concomitantly with the blood schizonticide because evidence indicates that this regimen results in greater efficacy in eradicating hypnozoites. However, if a delay occurs in determining the species or in obtaining G6PD testing results, primaquine still should be given even if shortterm treatment has been completed. Patients with G6PD deficiency who are not able to take primaquine should be retreated with chloroquine if relapses occur, or they should be given weekly chloroquine prophylaxis for 1 to 2 years. The recommended course of primaquine is 0.5 mg/kg daily for 14 days with a target total dose of >6 mg/kg. Patients weighing >70 kg can require treatment for >14 days to achieve the target total dose. Failure of primaquine to eradicate hypnozoites is very unusual if this total dose is attained. However, in many cases adherence to treatment cannot be ensured. If relapse occurs, the patient should be retreated with chloroquine and primaquine. Primaquine should not be used during pregnancy. People with decreased activity of hepatic isoenzyme 2D6 may not produce a sufficient quantity of the active metabolite of primaquine, thus resulting in occasional instances of primaquine failure.[37]

Physicians desiring consultation regarding the management of patients with malaria can call the Malaria Branch of the CDC at 770-488-7788 during working hours or at 770-488-7100 during nights and weekends. Up-to-date treatment recommendations also are available on the CDC website at https://www.cdc.gov/malaria/diagnosis_treatment/index.html.

Prevention

Travelers to endemic areas can prevent malaria through the use of chemoprophylaxis and personal protective measures such as insect repellents. The risk of acquiring malaria is highest in sub-Saharan Africa and Oceania and is more variable for other regions. The evolving picture of drug resistance complicates recommendations for chemoprophylaxis. Malaria prophylaxis recommendations are available in the biannual publication *Health Information for International Travel* and at the CDC malaria website at www.cdc.gov/malaria. Breastfed infants should receive appropriate malaria prophylaxis because they will not receive enough drug in milk to protect them.

Chloroquine (or hydroxychloroquine) can be used for prophylaxis in areas where chloroquine resistance has not been reported. Primaquine is the drug of choice for areas where *P. vivax* is the predominant malaria species (Table 271.2). Chloroquine is available only in tablet form in the US, and it tastes bitter when crushed. Reported side effects include gastrointestinal disturbance, headache, dizziness, blurred vision, insomnia, and pruritus, but often these effects do not require that the drug be discontinued. Chloroquine has been reported to exacerbate psoriasis.

Drugs Used in the Prophylaxis of Malaria

Drug	Usage	Adult Dose	Pediatric Dose	Comments
Atovaquone-proguanil (Malarone)	Prophylaxis in all areas	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride 1 adult tablet orally, daily	Pediatric tablets contain 62.5 mg atovaquone and 25 mg proguanil hydrochloride 5–8 kg: ½ pediatric tablet daily 9–10 kg: ¾ pediatric tablet daily 11–20 kg: 1 pediatric tablet daily 21–30 kg: 2 pediatric tablets daily 31–40 kg: 3 pediatric tablets daily 41 kg or more: 1 adult tablet daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Atovaquone-proguanil is contraindicated in patients with significant renal impairment (creatinine clearance <30 mL/min). Atovaquone-proguanil should be taken with food or a milky drink. Atovaquone-proguanil is recommended for children weighing 5 kg, pregnant women, and women breastfeeding infants weighing <5 kg

Chloroquine phosphate (Aralen and generic)	Prophylaxis only in areas with chloroquine-sensitive *Plasmodium falciparum*	500 mg (salt) orally, once/wk	8.3 mg(salt)/kg orally, once/wk, up to maximum adult dose of 500 mg (salt)	Begin 1–2 wk before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 wk after leaving such areas. Chloroquine can exacerbate psoriasis
Hydroxychloroquine sulfate (Plaquenil)	An alternative to chloroquine for prophylaxis only in areas with chloroquine-sensitive malaria	400 mg (salt) orally, once/wk	6.5 mg(salt)/kg orally, once/wk. Maximum dose = adult 400 mg salt	Begin 1–2 wk before travel to malarious region. Take weekly on the same day of the week while in malarious area and for 4 wk after leaving malaria endemic area
Doxycycline (many brand names and generic formulations)	Prophylaxis in all areas	100 mg orally, daily	≥8 yr of age: 2.2 mg/kg up to adult dose of 100 mg/day	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 4 wk after leaving such areas. Doxycycline is contraindicated in children <8 yr of age and in pregnant women
Mefloquine (Lariam and generic formulations)	Prophylaxis in all areas	250 mg (salt) orally, once/wk	≤9 kg: 5 mg(salt)/kg orally, once/wk 10–19 kg: ¼ tablet once/wk 20–30 kg: ½ tablet once/wk 31–45 kg: ¾ tablet once/week ≥46 kg: 1 tablet once/wk	Begin at least 2 wk before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 wk after leaving such areas. Mefloquine is contraindicated in patients allergic to mefloquine or related compounds (e.g., quinine and quinidine) and in patients with active depression, recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in patients with psychiatric disturbances, or a previous history of depression. Use is not recommended for patients with cardiac conduction abnormalities
Primaquine	Prophylaxis in areas with	52.6 mg (salt) orally, daily	0.8 mg(salt)/kg up to adult	Begin 1–2 days before travel to malarious areas.

	mainly *P. vivax* malaria		dose orally, daily	Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Contraindicated in patients with G6PD deficiency. Also contraindicated during pregnancy and lactation unless the infant being breastfed has a documented normal G6PD level

G6PD, glucose-6-phosphate dehydrogenase.

For people traveling to areas with malaria transmission where drug resistance other than chloroquine resistance is not a concern, atovaquone-proguanil, doxycycline, and mefloquine are equally recommended prophylactic options (see Table 271.2).

Atovaquone-proguanil should be taken daily with food to improve absorption. Because atovaquone-proguanil is considered a causal prophylactic agent (i.e., kills the initial hepatic stage of parasites), it must be given for only 7 days after leaving a malarious area. The most common adverse effects reported in people using atovaquone-proguanil for prophylaxis include abdominal pain, nausea, vomiting, and headache. Atovaquone-proguanil should not be used in children weighing <5 kg, pregnant women, women breastfeeding infants who weigh <5 kg, or patients with significant renal impairment (creatinine clearance <30 mL/min). Daily doxycycline is another option for travelers who are ≥8 years old (see Table 271.2). Gastrointestinal complaints, photosensitivity, and candidal vaginitis are reported adverse effects. Doxycycline should be taken with an ample amount of fluid and should not be taken before sleep to minimize the risk of esophagitis. Photosensitivity associated with the use of doxycycline can be lessened with sunscreen use. Doxycycline is contraindicated during pregnancy.

Mefloquine can be used in children of any weight (see Table 271.2). It is taken weekly. Nausea and vomiting have been problematic in children. Other reported side effects include headache, insomnia, abnormal dreams, visual disturbances, depression, anxiety disorder, and dizziness. Rare serious adverse reactions include acute reversible neuropsychiatric reactions, seizures, and cardiac conduction abnormalities. Mefloquine is safe to use in pregnancy (FDA pregnancy category B). Mefloquine is contraindicated in patients with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures (but not including typical febrile seizures). Mefloquine should be used with caution in patients with previous psychiatric disturbances or a previous history of depression. The drug is not recommended for patients with cardiac conduction abnormalities. Resistance to mefloquine has been reported in Southeast Asia, where doxycycline or atovaquone-proguanil should be used for prophylaxis.[38]

Travelers who reject the advice to take prophylaxis, who choose a suboptimal drug regimen (e.g., chloroquine in an area with chloroquine-resistant *P. falciparum*), or who require a less than optimal drug regimen for medical reasons are at greater risk for acquiring malaria. In addition, some travelers who are taking effective prophylaxis but who will be in very remote areas can decide, in consultation with healthcare personnel, to carry a reliable supply of a full course of an approved malaria treatment regimen. In the event that these travelers are diagnosed with malaria, they will have immediate access to this appropriate treatment regimen, which, if acquired in a developed country, is unlikely to be counterfeit and will not deplete local resources. In rare instances when access to medical care is not available and the traveler develops a febrile illness consistent with malaria, the reliable supply medication can be self-administered empirically. Travelers should be advised that this self-treatment of a possible malarial infection is only a temporary measure and that prompt medical evaluation is imperative.

Two malaria treatment regimens can be prescribed as a reliable supply: atovaquone-proguanil and artemether-lumefantrine. The use of the same or related drugs that have been taken for prophylaxis are not recommended to treat malaria. For example, atovaquone-proguanil can be used for treatment by travelers not taking atovaquone-proguanil for prophylaxis.

Avoidance of mosquitoes and barrier protection are critical aspects of malaria prophylaxis given that no chemoprophylaxis guarantees complete protection. Anopheline mosquitoes feed from dusk to dawn. Avoiding nighttime exposure by staying in screened-in or air conditioned areas, using protective clothing, sleeping under insecticide-treated bed nets, and using insect repellents all are helpful. Topical mosquito repellents that contain *N*-*N*-diethyl-*m*-toluamide (DEET) or picaridin are the most effective in preventing malaria.[39] Permethrin-impregnated bed nets are effective, and permethrin sprays are available for use on clothing.

None of these measures is 100% effective, and therefore the diagnosis of malaria should be considered in anyone with a fever who has been in an endemic area. Most travelers in whom malaria is diagnosed manifest symptoms within a few weeks to months after return from the malaria-endemic area, particularly with *P. falciparum* infection. Infections with the other species of malaria can appear months later. For people emigrating from malaria-endemic areas, manifestations of *P. falciparum* infection rarely occur after 1 year, whereas manifestations of infection with the other species of *Plasmodium* can occur years later.

Pregnancy increases the risk of complications from malaria in both nonimmune and partially immune women. The clinical course of the disease in these women can be more severe, and malaria during pregnancy carries an increased risk of premature birth or pregnancy loss. Pregnant women should avoid travel to malaria-endemic areas. If they must travel, chloroquine or mefloquine prophylaxis can be used during pregnancy. Atovaquone-proguanil, doxycycline, and primaquine are not recommended for use during pregnancy. Human data on atovaquone-proguanil are insufficient to recommend the use of this drug combination in pregnancy (pregnancy category C), whereas doxycycline is a known teratogen (pregnancy category D). Primaquine is contraindicated because of the theoretical risk of hemolysis in the fetus, if the fetus is G6PD deficient.

Traveling with children requires special preparation. In the US, antimalarial drugs are available only in tablet form, and most taste bitter. Compounding pharmacies can pulverize tablets, weigh out the precise dose, and place the dose in a gelatin capsule; sufficient time will be needed before travel to allow preparation of appropriate dosages. The capsule can be opened at the time of administration, and the medication can be mixed with sweet food items (e.g., applesauce, chocolate syrup, or jelly) to disguise the taste.[39]

Key Points

Epidemiology, Clinical Features, Diagnosis and Treatment of Malaria

Epidemiology

- Parasitic disease transmitted by anopheline mosquitoes
- Predominately in tropical climates
- 198 million cases/year
- 584,000 deaths/year, mostly in children <5 years of age
- Most deaths are caused by *Plasmodium falciparum,* and 90% occur in sub-Saharan Africa.
- In the US, most cases occur in people who have traveled to or emigrated from endemic areas.

Clinical Features

- High fevers and rigors
- Nonspecific symptoms such as myalgia, headache, arthralgia, fatigue
- Abdominal pain, diarrhea, vomiting
- Declining mental status a possible sign of cerebral malaria

Diagnosis

- Malaria should be suspected in anyone with fever who was in an endemic area within the past year.
- Microscopic examination of thick or thin blood films detects parasites.
- Rapid diagnostic tests should be available if microscopy is not available on site.

- Polymerase chain reaction can be used to aid in speciation.

- Thrombocytopenia is very common.

Treatment

- Severe malaria (acquired in any region)
  - Quinidine IV followed by tetracycline, clindamycin, or doxycycline; *or*
  - Artesunate IV (investigational drug available by consultation with the CDC), followed by atovaquone-proguanil, mefloquine, or doxycycline
  - See Table 271.1 for doses, duration, and age specifications
- Uncomplicated malaria
  - Consider prophylaxis regimen taken
  - Consider area of travel and resistance patterns
  - Consider species of *Plasmodium* identified
  - Consider age of patient and pregnancy status
  - See Table 271.1 to tailor therapy to the foregoing specifications

CDC, Centers for Disease Control and Prevention; IV, intravenously.

Sarcocystis Species

Douglas H. Esposito

Sarcocystis species are zoonotic protozoan parasites of the phylum Apicomplexa. Since it was first described in 1843, >150 species have been reported from a range of wild and domestic mammals, birds, and reptiles.[1] The organism requires a definitive host and an intermediate host to complete its life cycle.[1,2] Definitive-host infection is limited to the gastrointestinal tract (intestinal sarcocystosis), whereas intermediate-host infection leads to the formation of characteristic intramyocytic cysts (sarcocysts) for which the organism was named (Fig. 272.1). Although this infection was once considered rare in humans, outbreaks of symptomatic intermediate-host disease (muscular sarcocystosis) among tourists in Malaysia suggest that *Sarcocystis* species infection may be of increasing public health importance.[1]

Pathogen

Humans are the natural definitive hosts for 2 known *Sarcocystis* spp., *S. hominis* and *S. suihominis*, of which cattle and pigs, respectively, are the natural intermediate hosts (Fig. 272.2).[1,2] Humans acquire infection by eating raw or undercooked sarcocyst-containing meat. Only sexual stage parasites are found in definitive-host infections. In the small intestine, motile bradyzoites released from sarcocysts enter cells of the mucosa, where they transform into either a macrogamont (female) or a microgamont (male). Once fertilized, each macrogamont develops into an oocyst that sporulates, to form a pair of sporocysts, each containing 4 sporozoites (Fig. 272.3). Oocysts enter the intestinal lumen and fracture into individual sporocysts, either before or after being shed in the feces.

Humans are aberrant intermediate hosts for *S. nesbitti* (a species with a reptile as its likely definitive host) and possibly for other, unidentified *Sarcocystis* spp. (Fig. 272.4).[1,3–7] In intermediate-host infections, only asexual stage parasites are found.[1,2] Infection is acquired by ingesting food or water contaminated with feces from a sporocyst-shedding definitive host. In the small intestine, sporocysts excyst, releasing their 4 motile sporozoites, which penetrate the gut wall and enter the vasculature. There the sporozoites disseminate and undergo cycles of asexual development (merogony or schizogony) within the vascular endothelium of all parts of the body, first in small arterioles, then in capillaries, and finally in veins. Ultimately, the parasite enters myocytes of skeletal, smooth, or cardiac muscle where it forms bradyzoite-containing sarcocysts.

Epidemiology

Human intestinal sarcocystosis is distributed worldwide, but prevalence is not well characterized and may vary regionally.[1,8] Infection rates of >90% have been reported in cattle and pigs, the intermediate hosts for human infection, a finding suggesting high burdens of infection among people living in certain areas.

Before the 21st century, <100 cases of human muscular sarcocystosis had been reported in the literature, and most of these cases were diagnosed incidentally in asymptomatic people.[1,9] Distribution was worldwide, although most cases were from tropical and subtropical zones, nearly one half from Malaysia alone. No more than 10 cases were reported to be symptomatic intermediate-host infections.[1,4]

More recently, 2 large, unrelated outbreaks of symptomatic muscular sarcocystosis were reported among tourists to Pangkor and Tioman Islands in Malaysia.[4,10,11] Investigators identified *S. nesbitti* as the causative species in both outbreaks[3,4]; previously, all infections in humans were of unknown species.[1,2] Consumption of contaminated water was the likely source of infection for both outbreaks.[4,10,12,13]

Clinical Manifestations

Most people with intestinal sarcocystosis are asymptomatic or only mildly symptomatic, although severe illness can occur.[1,14] Symptoms can include fever, nausea, vomiting, abdominal cramping and distention, and diarrhea. The nature and severity of illness can depend on the number and species of sporocysts ingested.[1,2] Severe or disseminated infections among immunocompromised people can occur.[15]

Because so few symptomatic cases have been reported, characterization of the clinical manifestations of human muscular sarcocystosis is incomplete. Although infection can be asymptomatic or subclinical, severe, debilitating illness lasting weeks to months, and rarely years, has been reported.[1,9,16–18] Clinical variability can depend on many factors, including the infecting species, the infectious load, and host factors such as immunity and immune status.[1] Overall, the most common symptoms reported include fever, fatigue, myalgia, headache, cough, and arthralgia.[4,10,17] Less frequent are wheezing, nausea, vomiting, diarrhea, rash, lymphadenopathy, and symptoms reflecting cardiac involvement such as palpitations. Fever and muscle pain, sometimes relapsing, can occur in 2 distinct phases: early (beginning during the second week) and late (beginning during the sixth week) after infection.[4] Early-phase disease is characterized by nonspecific symptoms and laboratory abnormalities (e.g., lymphocyte count, liver functions, and lactate dehydrogenase),[4,10,11] and it may reflect generalized vasculitis associated with migration and development of the parasite within the vasculature.[1,4] Later, development of muscle tenderness, eosinophilia, and elevated serum creatinine phosphokinase levels can coincide with the onset of diffuse focal myositis.[4]

Diagnosis

Intestinal sarcocystosis should be considered in patients with enteritis and a history of having eaten raw or undercooked meat.[1] Confirmation relies on light or fluorescence microscopic observation of oocysts or sporocysts in stool; polymerase chain reaction is not widely available.[1,8]

The diagnosis of muscular sarcocystosis during the early phase of infection is made difficult by the lack of specificity of symptoms and clinical and laboratory findings, but it should be considered in patients with myalgia, with or without fever, and a history of travel to a tropical or subtropical region, especially Malaysia.[1,4,8] In the absence of alternate diagnoses such as influenza, dengue, or malaria, serial clinical and laboratory investigations for evidence of developing myositis and eosinophilia should be considered.[1,4] In patients with myositis, trichinellosis should be excluded. Confirmation of muscular sarcocystosis requires histologic observation of sarcocysts in muscle. Polymerase chain reaction is not widely available, and standardized serologic assays validated for use in humans do not currently exist.[1]

Treatment and Prevention

Human intestinal sarcocystosis is largely self-limited, and no specific treatment is available. No proven treatment exists for human muscular sarcocystosis. One patient treated with albendazole was reported to have improved, but whether this improvement was related to treatment or to the natural course of infection was not clear.[17] Co-trimoxazole, a drug with known antiprotozoal activity, may have activity against schizonts in the early phase of infection.[1,18] Glucocorticoids and nonsteroidal anti-inflammatory medications may improve symptoms associated with myositis.[4,10,11]

Thorough cooking or freezing of meat kills bradyzoites and prevents intestinal sarcocystosis.[1,2] To prevent muscular sarcocystosis, ingestion of sporocysts must be avoided.[1]

Toxoplasma gondii (Toxoplasmosis)

Despina Contopoulos-Ioannidis, José G. Montoya

Toxoplasma gondii is a parasite with worldwide distribution. Although frequently subclinical, *primary* infection can result in a spectrum of manifestations from a mononucleosis-like syndrome to severe ocular disease in immunocompetent people, in significant neurologic and ocular sequelae in congenitally infected fetuses and children, and, in certain tropical areas, in pneumonia, disseminated disease, and even death among otherwise healthy people.[1,2] In addition, *reactivation* of chronic infection can occur in severely immunosuppressed people and can cause life-threatening disease. Patients with profound T-lymphocyte–mediated immune compromise are at higher risk, including patients with acquired immunodeficiency syndrome (AIDS),[3] hematopoietic stem cell transplant (HSCT) recipients,[4] seronegative solid-organ transplant recipients in whom a seropositive allograft is implanted,[5] patients receiving high doses of corticosteroids and, likely, monoclonal antibodies such as alemtuzumab, adalimumab, or infliximab.[6–8] Chronic infection can have more longterm consequences than thought previously; several investigators are addressing the possible impact of latent infection on psychiatric disorders and abnormal behaviors.[9]

The term *T. gondii infection* is used when referring to asymptomatic primary or chronic infection, and *toxoplasmosis* is used when primary infection or reactivation of chronic infection causes signs or symptoms.

Pathogen and Life Cycle

T. gondii is an obligate intracellular parasite with the capacity to infect almost any warm-blooded animal. The parasite has 3 infectious stages: *tachyzoites,* which are responsible for rapid spread of the parasite between cells and tissues and for the clinical manifestations of toxoplasmosis; *bradyzoites,* which are contained within tissue cysts, maintain chronic infection, and stay dormant for the life of the host unless the immune system is severely compromised; and *sporozoites,* which are contained within oocysts, are shed by members of the felid family, and widely disseminate the agent in the environment.[10] A sexual cycle takes place only in the small intestine of felids, thus allowing for the exchange of genetic material among strains and potentially generating variant strains in geographic areas where wild and large cats can travel long distances.[11,12]

The genome of *T. gondii* is available at http://toxodb.org. Genotyping studies have allowed the identification of several clonal lineages in Europe, North America, and South America. Clonal lineages I, II, and III appear to be the most common strains observed in these areas; lineage II is predominantly seen in Europe, whereas in North America lineages I, II and III are implicated in human disease, and an additional new clonal lineage IV (type 12) has been identified[13]; in South America lineages I and III are reported predominantly.[14] In addition, atypical strains that do not fall within the 3 main clonage lineages are observed more commonly in North and South America. Strains from clonage lineage I and IV and atypical strains have been implicated in more aggressive disease in humans.

Investigators have suggested that differences in *T. gondii* strains may at least partially explain the observed differences in the clinical spectrum of infection, particularly among Europe, North America, and South America. Atypical *T. gondii* strains have been reported from several additional areas of the world including Central and South America, Australia, and Africa. This finding should be taken into consideration when clinical syndromes consistent with severe toxoplasmosis are encountered in people returning from these areas. Significant differences in the prevalence and severity of major manifestations (e.g., chorioretinitis, brain calcifications, and hydrocephalus) have been observed in the United States, France, other Western European countries, and South America. For example, the ocular manifestations of congenital toxoplasmosis in children in Brazil are more severe than those in children in Europe.[15–18] Primary infections in adults have resulted in pneumonia, acute hepatitis, fever of unknown origin, and death in human immunodeficiency virus (HIV)–negative and immunocompetent people in South America.[1]

Cats, both domestic and wild, are the definitive hosts, host the complete life cycle, and are responsible for widespread existence of the parasite throughout the world. Most cats are asymptomatic during *T. gondii* oocyst shedding. Cats shed oocysts following the ingestion of any of the infectious stages of the parasite, tissue cysts, and oocysts. As many as 10 million oocysts can be shed in a single day in the cat's feces, for periods varying from 7 to 20 days. Oocysts can remain viable in moist soil for as long as 18 months. Other felids and intermediate hosts including humans can acquire infection from this environmental source. Eating meat of infected rodents, birds, or other animals also can infect cats, and the consumption of infected meat can infect humans.

Epidemiology

Population seroprevalence of *T. gondii* varies by geographic locale, thus reflecting the likelihood of having been exposed to oocysts in soil, untreated water, vegetables, raw shellfish, and other food items and to tissue cysts in uncooked or raw meat.[19–21] The age-adjusted seroprevalence of *T. gondii* infection in the US according to the most recent national survey (2009–2010) was 12% for people >6 years of age and 9% for women of childbearing age (15–44 years)[22]; however, even in the US, seroprevalence can be as high as 20% to 25% within certain socioeconomic and racial or ethnic subgroups. Seroprevalence in other parts of the world can be 60% to 80% (e.g., in Central and South America).[23–25] In most countries, including the US, prevalence is declining, whereas in certain areas of the world prevalence is stable or increasing. In all areas, seroprevalence increases with age (reflecting additive exposure) and usually is associated inversely with socioeconomic status, a reflection of a strong influence of hygienic and alimentary habits in transmission.

Humans and other vertebrates are incidental hosts and become infected primarily by the oral route through ingestion of environmental oocysts or infected meat containing tissue cysts (Fig. 273.1). Vertical transmission occurs during gestation. Humans also can acquire infection through receipt of an organ transplant from an infected donor and, more rarely, during a laboratory accident. Main risk factors for acute *T. gondii* infection in the US identified in a study published in 2009 were as follows: eating raw ground beef, rare lamb, or locally produced cured, dried, or smoked meat; working with meat; drinking unpasteurized goat milk; or living with ≥3 kittens.[20] An additional novel risk factor identified in this study was eating raw oysters, clams, or mussels. Drinking untreated water also showed increased risk but was not statistically significant.[20] Untreated water has been reported to be the source of major community outbreaks of acute toxoplasmosis in Canada and Brazil.[26,27] Family clusters of acute toxoplasma infections have also been documented in the US.[28,29] In up to 50% of patients with confirmed acute *T. gondii* infection, no known risk factors are identified.[30,31]

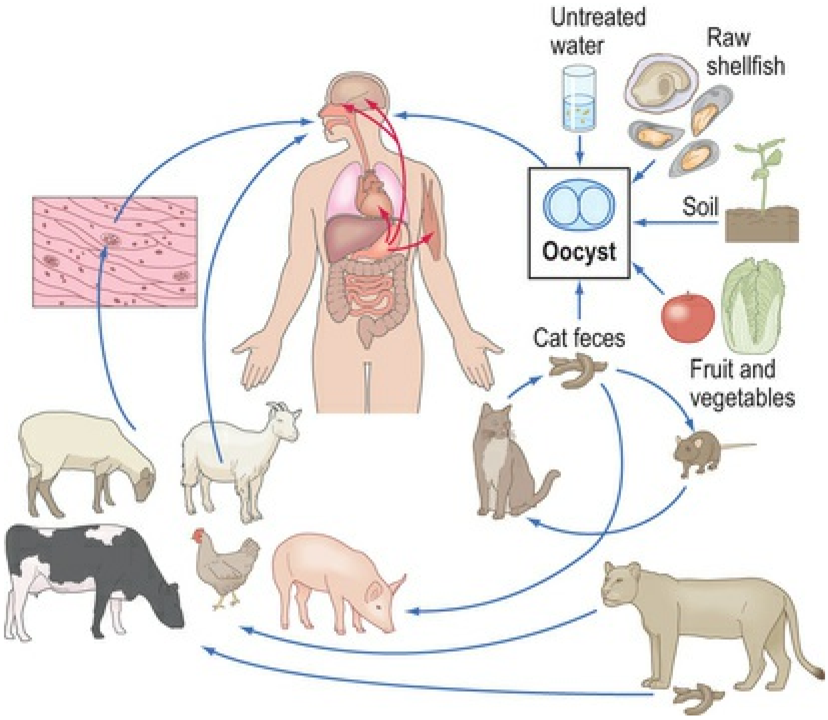

FIGURE 273.1 Life cycle of *Toxoplasma gondii.*

Congenital infection usually is the result of a woman's acquiring primary infection during gestation or within 3 months before conception. If significantly immunocompromised (e.g., by AIDS), previously infected women can reactivate infection during gestation and transmit the parasite to their children.[32–34] Rare but well-documented cases are reported of previously infected healthy women who acquired a more virulent strain of *T. gondii* during gestation and gave birth to an infected infant.

The incidence of acute primary *T. gondii* infections during gestation in the US in the early 1960s was estimated to be 1.1 in 1000 pregnant women.[35] More recent surveillance data in the US are not available, but the overall decrease in seroprevalence suggests that the current incidence of acute *T. gondii* infections during pregnancy is likely to be much lower. Most Western European countries report rates of seroconversion during pregnancy between 0.5 and 2.1 in 1000 pregnant women,[36] whereas in other parts of the world these rates remain high (e.g., 4.8 in 1000 women in South America[37]).

The overall rate of transmission to the fetus in women who seroconvert during gestation has been reported to be between 50% and 60% before the introduction of spiramycin and 25% to 30% thereafter.[2] The rate of vertical transmission increases and the severity of disease decreases with advancing gestational age at the time of maternal infection (Fig. 273.2).[38] In treated women, vertical transmission rates can be as low as 6% at 13 weeks of gestation, 40% at 26 weeks, and 72% at 36 weeks (see Fig. 273.2A).[38] More recently reported rates of mother-to-child transmission from France (where spiramycin therapy was begun in the 1970s) are similar (11%, 47%, and 64%, respectively).[39] In treated women, the risk of clinical signs in their infected fetus has been estimated at 56% if infection was acquired at 12 weeks of gestation, 17% if acquired at 24 weeks, and 9% if acquired at 36 weeks[39] (see Fig. 273.2B).[38]

The incidence of congenital toxoplasmosis in the US, according to early reports from the New England newborn Screening Program (1986–1992), was estimated to be 0.82 cases in 10,000 live births,[40] and from 2006 to 2014 the incidence decreased to approximately 0.23 cases in 10,000 live births (Hsu Ho-Wen, personal communication from the Massachusetts Department of Public Health, 2015). However, the true incidence of congenital infection may be higher because the sensitivity of the newborn screening test (filter paper blot spot anti-*Toxoplasma* immunoglobulin M [IgM]) used is only 50% to 75%, and fetal losses were not counted.[40,41]

The incidence of congenital toxoplasmosis at birth in France in 2007 was 2.9 cases in 10,000 live births,[42] whereas the prevalence was 3.3 cases in 10,000 live births, and the incidence of symptomatic congenital toxoplasmosis was 0.34 cases in 10,000 live births. The global burden, however, is estimated to be 190,000 cases of congenital toxoplasmosis annually, with an overall incidence of 15 cases in 10,000 live births. The incidence of congenital toxoplasmosis in certain world regions (e.g., South America) is as high as 18 to 34 cases in 10,000 live births.[43] The severity of disease also is higher in these regions.[44]

Pathogenesis and Immune Response

Following oral ingestion of tissue cysts (e.g., in infected meat) or oocysts (e.g., from contaminated soil, water, or food), gastric juices disrupt cyst walls and release bradyzoites (from tissue cysts) and sporozoites (from oocysts), which are converted to tachyzoites. Because of their capacity to move by gliding, flexing, undulating, and rotating, tachyzoites easily infect contiguous cells. Tachyzoites also can infect distant tissues by hematogenous or lymphatic spread. Tachyzoites likely infect Peyer patches and the spleen first, followed by the lungs and liver. Parasitemia can be detected for several days during the early stages of acute infection and probably lasts for approximately 14 days before IgG antibodies are detected. Tachyzoites ultimately arrive at sites such as the brain, eye, heart, and skeletal muscle where, under the pressure of the immune system and other factors, they convert to bradyzoites.

In immunocompetent hosts, an effective immune response controls the proliferation of the rapidly replicating tachyzoite, induces conversion to the metabolically slower bradyzoite, and facilitates formation of tissue cysts (chronic infection). Tissue cysts likely persist for the life of the host, most commonly in the brain, retina, and cardiac and skeletal muscles. Innate, humoral, and cellular immune responses are required to prevent the uncontrolled proliferation of tachyzoites, including the activation of the following: the monocyte-macrophage system, dendritic cells, natural killer cells, and *T. gondii*–specific and cytotoxic $CD4^+$ and $CD8^+$ T lymphocytes; and interferon γ, interleukin-12, tumor necrosis factor-α, interleukin-10 and other cytokines, transforming growth factor-β, costimulatory molecules (e.g., CD28, CD40 ligand), and, to a lesser degree, immunoglobulins.[45]

In immunocompromised patients previously infected with *T. gondii,* significant depletion of T-lymphocyte–mediated immune responses can facilitate reactivation of infection.

Clinical Manifestations

Toxoplasmosis should be considered in the differential diagnosis of several clinical syndromes in immunocompetent children, congenitally infected infants, and immunocompromised children. Signs and symptoms result from primary infection or reactivation. In both forms, the rapid proliferation of the tachyzoite and its corresponding inflammatory immune response are responsible for clinical manifestations. Primary infection can be asymptomatic in many infants and children, and conventional risk factors for the acute infection may not be present in a particular patient.[30] If the goal is to detect each case of primary *T. gondii* infection in a given population of patients (e.g., pregnant women) or to diagnose toxoplasmosis in an ill patient, laboratory testing is necessary. Testing of only symptomatic patients or patients with conventional epidemiologic risk factors misses a substantial portion of acute cases (~50%).[30,31]

The severity of toxoplasmosis during primary infection or reactivation can be influenced by the genetics of the infecting strain,[46] inoculum size, infectious form (e.g., oocyst vs. tissue cyst), immunocompetence, genetics of the host (e.g., presence of human leukocyte antigen [HLA]-DQ3), and, particularly for congenital toxoplasmosis, the absence of prenatal or postnatal treatment.[16,18,39,47–50] Reports from several large observational studies provide supportive evidence for the efficacy of prenatal screening and treatment programs in reducing the mother-to-child-transmission risk and the severity of congenital toxoplasmosis.[39,44,47–50]

Primary Infection in Immunocompetent Children, Adults, and Pregnant Women

Although most children and adults are asymptomatic at the time of primary infection, in ~10% of patients, the following symptoms or syndromes, alone or in various combinations, have been reported: mononucleosis-like illness, fever (≤104°F or ≤40°C), lymphadenopathy, headache, myalgia, arthralgia, sore throat, stiff neck, nausea, abdominal pain, anorexia, confusion, eye symptoms including eye pain, general malaise, and fatigue; occasionally, skin rash and earache can occur. In community outbreak settings or in certain tropical areas, as many as 82% of infected people are symptomatic, and up to 19% can have eye disease.[26]

Lymphadenopathy can be localized or generalized. A solitary, occipital, and painlessly enlarged lymph node can be the sole manifestation of toxoplasmosis in a child, pregnant woman, or adult. However, more generalized lymphadenopathy (cervical, occipital, axillary, inguinal, mediastinal, and abdominal) can occur. Lymph nodes usually are 1 to 3 cm, nonsuppurative, and nontender, and the lymphadenopathy usually regresses within 3 months. Mild relapse of lymphadenopathy can occur between 3 and 6 months, but lymphadenopathy beyond then is rare and should suggest an alternate diagnosis.

Ocular toxoplasmosis as a manifestation of primary, postnatally acquired infection is more common than previously thought.[26,52] Chorioretinitis resulting in blurred vision, eye pain, decreased visual acuity, “floaters,” scotoma, photophobia, or epiphora can occur. People with postnatally acquired *T. gondii* also can develop chorioretinitis as a result of reactivation of previous infection. The morphologic features of *T. gondii* retinal lesions on funduscopic examination often are characteristic. An active whitish infiltrate usually is attached to the darkly pigmented border of an older scar. However, retinal lesions tend to be less typical in older and immunocompromised patients.

Other syndromes such as hepatitis, pneumonitis, myocarditis, and myositis are described. Disseminated disease, pneumonitis, and even death can occur in immunocompetent people infected with high parasite load and/or atypical strains of *T. gondii,* such as in Latin America.

Congenital Toxoplasmosis

In countries where serologic screening and prenatal treatment are offered systematically to pregnant women, most fetuses and newborns infected with *T. gondii* do not exhibit any clinical signs of disease on initial evaluation.[18] However, clinical manifestations of toxoplasmosis can be discovered years later. In cohorts of prenatally treated infants in France, initial eye lesions were detected at >7 months of age in 75% of affected children and at >3 years of age in 50% of congenitally infected children[53] (Fig. 273.3). In 34% of children, recurrences of eye disease or new eye lesions occurred up to 12 years after the first eye lesion.[53] In the US, among congenitally infected children whose mothers did not receive treatment during pregnancy, most fetuses and newborns are symptomatic,[15,17,18] and among infants who were not treated during their first year of life, >70% develop new chorioretinal lesions by 10 years of age.[54]

Congenital infection can result in fetal death or a wide variety of central nervous system and other organ abnormalities evident on fetal ultrasonography (Box 273.1). Clinical manifestations ascribed to congenital toxoplasmosis are shown in Box 273.2. Newborns can be asymptomatic or have any of the following clinical manifestations, alone or in combination: chorioretinitis, strabismus, blindness, hydrocephalus or microcephaly, seizures, encephalitis, hepatosplenomegaly, pneumonitis, hypothermia, jaundice, petechiae, skin rash, hearing loss.[2,17,55–57] Neurologic manifestation range from subtle signs to massive, acute encephalopathy. Intracranial calcifications can be present in brain imaging studies.

The classic triad of chorioretinitis, hydrocephalus, and brain calcifications is highly suggestive of toxoplasmosis and primarily is seen in neonates whose mothers were not treated during pregnancy.[15] More severe ocular disease is apparent in infants from certain parts of the world. For example, congenitally infected children in Brazil, compared with Europe, more frequently have chorioretinitis, multiple and larger eye lesions, and lesions located in the posterior pole that cause visual impairment and threaten vision.[16] These differences may be attributed to more virulent indigenous strains and/or infections with higher parasite load, and a lack of universal prenatal screening and treatment of pregnant women, or both.

Chronic Infection in Immunocompetent Children

During the chronic stage of infection, *T. gondii* does not appear to cause overt symptoms in most immunocompetent people. However, toxoplasmic chorioretinitis can develop in previously infected, immunocompetent people, most likely because of reactivation of the parasite and subsequent host immune response. Reactivation can occur in congenitally or postnatally infected people. Reactivation of congenital infection appears to occur more commonly between 10 and 30 years of age and is more likely to involve the macula bilaterally. In contrast, ocular disease resulting from reactivation of a postnatally acquired and latent infection appears to occur in people >50 years of age and is more likely to cause peripheral and unilateral retinal lesions.

Reactivation of Chronic Infections in Immunocompromised Patients

Reactivation of chronic infection in immunocompromised people can manifest as multiple brain abscesses, diffuse encephalitis, seizures, chorioretinitis, fever of unknown origin, pneumonitis, myocarditis, hepatosplenomegaly, lymphadenopathy, and skin rash. Some immunocompromised patients also can develop disseminated disease with a severe septic shock– like picture and multiorgan failure. Fever or pneumonia, or both, can occur as the only manifestation. Significant T-lymphocyte or B-lymphocyte deficiency must be present for children to reactivate infection secondary to immunosuppression, and it occurs in patients with AIDS or in allogeneic HSCT recipients. Use of monoclonal antibodies such as alemtuzumab, adalimumab, or infliximab[6–8] has been associated with symptomatic reactivation of latent infection (e.g., toxoplasmic encephalitis or chorioretinitis).

Diagnosis

Laboratory tests for the diagnosis of *T. gondii* infection and toxoplasmosis include serologic studies, polymerase chain reaction (PCR), histologic and cytologic examination of tissue and body fluids, and attempts to isolate the parasite in mice. Regardless of the presence or absence of symptoms, serologic tests can establish whether a patient is infected, and if infected, whether acutely or chronically. Clinically available serologic tools include methods to detect *T. gondii*–specific IgG, IgM, IgA, and IgE antibodies, the IgG-avidity, and differential agglutination (AC/HS) test.[58]

Acute and Chronic Infection

With the use of commercial kits for the detection of IgG and IgM, most laboratories can reliably diagnose the absence of *T. gondii* infection (negative IgG/negative IgM) or the presence of chronic infection (positive IgG/negative IgM). In contrast, the diagnosis of an acute infection cannot rest solely on a positive IgM test result. IgM antibodies are observed during acute infection but can remain positive for months to years without apparent clinical relevance. In addition, commercial IgM kits may not be specific.[59,60]

Of patients with positive IgM results at commercial laboratories, only 40% were confirmed to have a recent infection when their serum was tested at the National Reference Laboratory for the diagnosis of toxoplasmosis in the US Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL, Palo Alto, Calif; www.pamf.org/serology/; 650-853-4828; toxolab@pamf.org) with an additional comprehensive panel of tests. The remaining 60% of these patients were considered to have had a past infection.[59] At PAMF-TSL, a panel of confirmatory tests (IgG avidity, differential agglutination AC/HS test, IgM, IgA, IgE) is available in addition to the gold standard dye test for IgG and the IgM immunosorbent agglutination assay [ISAGA]. Currently, some commercial laboratories in the US offer the US Food and Drug Administration (FDA)–approved *Toxoplasma* IgG-avidity test and *Toxoplasma* IgA ELISA test. The tests at the National Reference Laboratory are used in various combinations (panels of tests), depending on the clinical situation and the specific clinical question. Serum with a positive IgM test result can be sent to the PAMF-TSL for confirmatory testing involving various combinations of the following tests: IgG dye test, IgG-avidity test, differential AC/HS agglutination test, IgM, IgA, and IgE. The appropriate choice of tests depends on the clinical situation and questions posed by the clinician. Final results at the PAMF-TSL can yield 3 interpretations : (1) *acute infection,* when results are consistent with a recently acquired infection; (2) *chronic infection,* when results are consistent with an infection acquired in the distant past (for older children this could also indicate a congenitally acquired infection); and (3) *unclear,* when results cannot exclude a recently acquired infection (in which case an earlier or subsequent sample is required to attempt to establish whether the infection is acute or chronic). For serologic test results consistent with an acute infection, an attempt should be made to establish the approximate date of infection to help determine whether a patient's clinical symptoms can be attributed to toxoplasmosis.

Definitive Diagnosis

The diagnosis of toxoplasmosis (caused by primary *T. gondii* infection or reactivation of chronic infection) requires the identification of tachyzoites in tissues or body fluids, the amplification of parasite DNA in any body fluid, or the visualization of tissue cysts surrounded by a pathologic inflammatory response. Tachyzoites can be visualized in histologic sections stained with hematoxylin and eosin or in cytologic preparations without any special staining, but are they best visualized with Wright-Giemsa and *T. gondii*–specific immunoperoxidase stains. Real-time PCR has become a useful method for the diagnosis of toxoplasmosis; a positive test result in amniotic fluid (AF) during gestation is diagnostic of fetal infection, in cerebrospinal fluid (CSF) of toxoplasmic encephalitis or congenital toxoplasmosis with central nervous system disease, in bronchoalveolar fluid of toxoplasmic pneumonia, in vitreous fluid of toxoplasmic chorioretinitis, and in peripheral blood, CSF, and urine of disseminated toxoplasmosis or of congenital toxoplasmosis. (However, a negative neonatal *T. gondii* PCR from blood, CSF, and/or urine does not exclude congenital toxoplasmosis.) Identification of the parasite in any body fluid is diagnostic of toxoplasmosis.

In certain clinical settings the diagnosis of toxoplasmosis can be made presumptively by positive results of *T. gondii*–specific serologic test along with characteristic histologic findings in a lymph node biopsy or retinal findings suggestive of ocular toxoplasmosis. Results of *T. gondii* PCR and parasite isolation can be falsely negative in patients receiving anti-*Toxoplasma* treatment. Particularly in cases of eye disease, reactivation (e.g., from congenitally or postnatally acquired infections), serologic testing may be nonspecific or not indicative of acute infection (e.g., positive *Toxoplasma* IgG antibody only). Reactivation of latent *T. gondii* infection in an immunocompromised patient (e.g., already known to be *T. gondii* seropositive) sometimes cannot be diagnosed serologically. Serologic test results in the posttransplant period are unreliable (antibody titers can remain the same, increase, or decrease) and are not helpful in excluding or establishing the diagnosis of reactivation. In these cases, PCR testing of body fluids/tissues (blood, bronchoalveolar lavage, CSF, urine, or other fluid/tissue) or histopathologic examination of stained tissue specimens for identification of tachyzoites can be diagnostic.

Diagnosis in Pregnancy

The diagnosis of toxoplasmosis during pregnancy is primarily accomplished by serologic testing for diagnosis of maternal infection, as well as AF PCR testing and fetal ultrasound examination for diagnosis of fetal infection. For appropriate interpretation of results, clinical information on the mother is required, including postconception age at testing, the presence of clinical signs and symptoms after or shortly before conception, and the presence of immunosuppression including HIV infection.

Maternal Serologic Tests

In countries where routine prenatal screening has been implemented, *Toxoplasma*-seronegative women are identified on their first prenatal visit and are screened monthly (e.g., France) or every 3 months (e.g., Austria, Germany, Italy) until delivery. Seroconversion during gestation is diagnostic of acquisition during pregnancy and is defined as a change from undetectable to detectable anti-*Toxoplasma* IgG.[2] In patients who seroconvert, the IgM test result becomes positive first, usually with a high level. In contrast, in countries where no routine prenatal screening is used, prenatal diagnosis of *T. gondii* infection or toxoplasmosis is based on a single serum sample tested during gestation.

In commercial laboratories, IgG-positive or IgG-negative results and IgM-negative results are reliable. If a pregnant woman has the ability to produce immunoglobulins and has negative IgG and IgM test results, no evidence of previous *T. gondii* infection exists; testing for *Toxoplasma* IgG and IgM every 4 to 8 weeks for the duration of the pregnancy is prudent. If the IgG test result is positive but at a low titer (e.g., near the cutoff of positivity for the IgG test or a dye test result at PAMF-TSL ≤1 : 512) and the IgM test result is negative, the patient most likely was infected at least 6 months before the date of testing. IgG-positive test results at high titers (e.g., IgG-dye test result ≥1 : 1024 at PAMF-TSL) even with negative IgM test results should be interpreted with caution with the assistance of medical consultants at reference laboratories and with performance of an additional panel of tests or follow-up serologic testing.

In pregnant women with positive toxoplasma IgG and IgM test results, the positive IgM test result alone cannot be used to confirm acute *T. gondii* infection or toxoplasmosis; additional confirmatory tests should be performed. The battery of tests used varies with the gestational age at which the serum sample was obtained. For women screened at <16 weeks of gestation, the more cost-effective panel contains the IgG dye test, IgM enzyme immunoassay (EIA), and IgG-avidity test. For women screened at >16 weeks of gestation, the AC/HS test is used in the panel instead for the IgG-avidity test. In most cases, results in these tests yield either of 2 interpretations: (1) infection acquired during or shortly before gestation or (2) infection acquired in the distant past before gestation. Sometimes when timing of infection cannot be accurately estimated by these tests, additional or follow-up testing is recommended. Follow-up testing could include IgG dye test, IgG avidity, AC/HS, IgM, IgA, or IgE.

If a pregnant woman has a negative IgG dye test result but a positive IgM test result, she may have been infected recently or may have a false-positive IgM result. Sera should be submitted to a reference laboratory for confirmatory testing; follow-up testing 2 to 4 weeks later may be required. Follow-up IgG dye test positivity would be diagnostic of seroconversion and of very recently acquired infection. In contrast, persistent IgG-dye test negativity (even if the IgM remains positive) suggests a false-positive IgM result.

Results of serologic test that are performed late (>20 weeks) in gestation can be difficult to interpret unless the woman is seronegative or the serologic test results clearly suggest an infection acquired in the distant past (before gestation). Assays sophisticated enough to make this distinction are limited to highly specialized laboratories such as the PAMF-TSL. With late maternal initial testing (unless the woman has clear serologic evidence of an acute *T. gondii* infection acquired late in gestation), usually it is not possible to exclude the possibility of an acute primary infection acquired early in gestation (unless a maternal serum obtained earlier in gestation is available for comparative serologic testing).

Polymerase Chain Reaction Testing on Amniotic Fluid

Once the diagnosis of acute *Toxoplasma* infection during pregnancy has been confirmed or highly suspected, the next step is to determine whether the fetus has been infected. AF PCR is the laboratory method of choice. The diagnostic accuracy of AF PCR varies according to the trimester of pregnancy during which maternal infection occurred (not the trimester during which amniocentesis was performed). A negative AF PCR result for an acute maternal infection that was likely acquired early in gestation can exclude fetal infection because the negative predictive value of AF PCR for such early maternal infections is high.[61] However, a negative AF PCR result for acute maternal infection likely acquired late in gestation should be interpreted with caution because the negative predictive value of AF PCR for such late infections is lower.[61] Nevertheless, a positive AF PCR result at any time during gestation is diagnostic of fetal infection and can be used to recommend treatment for fetal infection; the positive predictive value of AF PCR is essentially 100% in all trimesters, assuming that laboratory error is excluded.[61]

Independent of AF PCR results, all infants whose mothers were diagnosed with acute primary infection during gestation should undergo a postnatal evaluation to exclude congenital toxoplasmosis.

Diagnosis in the Neonate

The approach to evaluation for congenital infection is shown in Box 273.3. In the newborn, congenital toxoplasmosis can be diagnosed by the following: positive *Toxoplasma* IgG in addition to IgA or IgM antibodies; positive *T. gondii* PCR results on blood, urine, or CSF specimens; or parasite isolation from any body fluid (now rarely used). *Toxoplasma* IgE is not included in the routine neonatal panel of tests at the PAMF-TSL because it does not provide diagnostic information beyond what is already provided by the IgG, IgM (ISAGA) and IgA testing.

Evaluation of Infants With Suspected Congenital Toxoplasmosis

Serologic Screening

- **Toxoplasma IgG antibodies:** IgG dye test at PAMF-TSL, the national reference laboratory for toxoplasmosis in the US [gold standard]; IgG ELISA done in commercial laboratories

- **Toxoplasma IgM antibodies:** IgM ISAGA done at PAMF-TSL and toxoplasmosis reference laboratories is more sensitive than IgM ELISA, which is done at commercial laboratories; IgM ISAGA recommended for infants <6 months of age; a negative IgM ELISA result cannot exclude the diagnosis of congenital toxoplasmosis even if IgA antibodies are also negative

- **Toxoplasma IgA antibodies:** by ELISA or ISAGA

Toxoplasma Gondii Polymerase Chain Reaction Testing

- **PCR on sample of peripheral blood, urine, and CSF:** CSF examination should be considered in the following cases:

  - Infants with positive *T. gondii* IgG, IgM ISAGA, or IgA

  - Infants born to mothers with recently acquired *T. gondii* infection during pregnancy who had positive *T. gondii* AF PCR or abnormal fetal ultrasound findings suggestive of CT independently of whether antepartum treatment was received or not

  - Infants born to mothers with recently acquired *T. gondii* infection during pregnancy who have not received any antepartum anti-*Toxoplasma* treatment during pregnancy, and particularly those who likely had acquired the infection in the second or third trimester- (even if *T. gondii* AF PCR or fetal ultrasound results were negative)

- CSF PCR can sometimes be helpful in making the diagnosis of CT, even earlier than serologic testing alone (e.g., in cases of maternal infections acquired late in gestation), and in some instances it may be the only positive test result.

Cerebrospinal Fluid Analysis (Cell Count, Differential, Protein, and Glucose)

- Based on data from PAMF-TSL, there is no evidence to suggest that CSF serologic testing (CSF *Toxoplasma* IgG and IgM) could offer any incremental benefit from the information already gained from neonatal serology *plus* CSF cell count, differential, protein, and glucose *plus* CSF *T. gondii* PCR *plus* CNS imaging.

- CSF examination could be deferred in infants with very low suspicion of CT such as asymptomatic infants at birth who fulfill all the following criteria: their mothers had a diagnosis of acute *T. gondii* infection in the first trimester; their mothers had received prenatal treatment throughout gestation; AF PCR results were negative; monthly fetal ultrasound scans were normal; *and* the infants had negative *Toxoplasma* IgM ISAGA and IgA findings at birth.

Other Laboratory Tests

- Complete blood count and liver function tests

Clinical Evaluation

- Detailed physical examination at birth; every 2 to 3 months during the first year of life and every 4 to 6 months afterward

- Pediatric neurologic evaluation at birth; every 2 to 3 months during the first year of life and every 4 to 6 months afterward

- Pediatric ophthalmologic examination at birth and every 3 to 4 months (preferably by a retinal specialist) during the first year of life; every 4 to 6 months during the second year of life, and every 6 months during the third year of life for infants with CT (close ophthalmologic follow-up is indicated for infants with CT because the diagnosis of the onset of the first eye lesion can be delayed)

Imaging

- Head computed tomography (to evaluate for, e.g., intracranial calcifications, ventriculomegaly, hydrocephalus). Head MRI could also be considered, given the absence of radiation risk. (Head ultrasonography has been used mainly in European cohorts where the rate of symptomatic CT cases is very low compared with the United States)

- Abdominal ultrasound for intrahepatic calcifications or hepatosplenomegaly

Auditory Brainstem Responses

- Shortly after birth and yearly audiologic evaluation afterward for the first 3 years of life

AF, amniotic fluid; CNS, central nervous system; CSF, cerebrospinal fluid; CT, congenital toxoplasmosis; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; ISAGA, immunosorbent agglutination assay; PAMF-TSL, Palo Alto Medical Foundation Toxoplasma Serology Laboratory; PCR, polymerase chain reaction.

The preferred method for the detection of IgM antibodies in the newborn is the IgM ISAGA, and for IgA it is the enzyme immunoassay (EIA) or ISAGA technique.[62] The serum sample for serologic testing should be obtained from peripheral blood and not from cord blood because of the high rate of maternal blood contamination. Maternal blood contamination of the newborn's peripheral blood can occur during labor and maternal IgM and IgA antibodies can be detected in the neonatal blood the first 5 and 10 days of life, respectively. Thus a positive IgM ISAGA (after 5 days of life) or IgA ELISA (after 10 days) is diagnostic of congenital disease. Congenitally infected babies can be positive for both, positive for either, or occasionally negative for both. False-positive IgM ISAGA test results, particularly at low titers, can be seen in infants who have received transfusion of blood products. A positive anti–*T. gondii* IgM result in CSF is diagnostic of congenital disease, but testing of the CSF by PCR is strongly recommended because of its higher sensitivity.[63]

The diagnosis of congenital toxoplasmosis also can be made by a positive PCR test result in peripheral blood, CSF, urine, or other body fluid/tissue. The CSF also should be sent for CSF cell count, differential of white cells, and protein and glucose analysis. CSF of congenitally infected infants can have high levels of protein (up to 1000 mg/dL), hypoglycorrhachia, and eosinophilia in addition to mild to moderate lymphocytosis. Brain imaging studies can reveal calcifications, ventriculomegaly, or hydrocephalus; computed tomography is superior to ultrasonography for detection of central nervous system calcifications. Head MRI could also be considered for the initial evaluation, because it obviates the risk of radiation; however, empirical comparative data versus other imaging studies are lacking. Calcifications also can be detected in the liver by abdominal ultrasound.

Persistence of *Toxoplasma* IgG in a child ≥12 months of age is diagnostic of congenital toxoplasmosis and is considered the gold standard for definitive laboratory diagnosis. Maternal transplacentally transferred IgG antibodies usually disappear after 6 to 12 months of life. Initially, the titer of the IgG antibody in the infant should be similar to that of the mother. Then, the noninfected infant's IgG titers decrease according to the half-life of the IgG (~4 weeks); *Toxoplasma* IgG titer should decrease by at least 50% every month. Quantification of enzyme immunoassay values is less reliable. In performing serial testing, the infant's specimens should be tested in parallel, and expert consultation should be sought at reference laboratories. The kinetics of the child's IgG may be affected by treatment for toxoplasmosis. Disappearance of *Toxoplasma* IgG at <12 months of age, in the absence of anti-*Toxoplasma* treatment in an infant capable of producing normal levels of IgG, excludes the diagnosis of congenital toxoplasmosis.

Diagnosis in Immunocompetent Children

Systemic Disease

If an immunocompetent patient with suspected toxoplasmosis has negative IgG and IgM test results, symptoms or signs should not be attributed to infection with *T. gondii*. If the serologic test results are consistent with a chronic infection, use of a reference laboratory can help to determine a minimum window of timing of infection to establish relevance to clinical manifestations. Most immunocompetent children do not have clinically apparent reactivation of chronic infection. Ocular disease is an exception and can reactivate in immunocompetent children up to early adulthood. In addition, chronic *T. gondii* infection has been hypothesized to play a role in mental illness and behavior in infected animals and humans. Further investigation is required.

Lymphadenopathy caused by to toxoplasmosis can result in a virtually pathognomonic histologic pattern of findings, including reactive follicular hyperplasia, irregular clusters of epithelioid histiocytes encroaching on and blurring the margins of the germinal centers, and focal distention of sinuses with monocytoid cells.[64]

Ocular Disease

The diagnosis of acute postnatally acquired ocular disease can be made if *Toxoplasma* IgG and IgM antibodies are present in the serum and ocular symptoms started approximately at the same time as the infection was acquired. If serologic test results are consistent with distantly acquired infection, ocular symptoms can be ascribed presumptively to reactivation of *T. gondii* infection (acquired either congenitally or postnatally in the distant past), assuming that the morphologic features of the retinal lesions are characteristic (see Fig. 273.3) and the response to therapy for toxoplasmosis is adequate. In patients whose lesions are not typical of toxoplasmosis or who have a suboptimal response to therapy, sampling of ocular fluids for diagnosis should be considered.

Sampling of the aqueous humor, rather than vitreous fluid, has a lower risk of adverse events. The immune load (Goldmann-Witmer coefficient analysis of aqueous humor) is calculated as anti–*Toxoplasma*-specific IgG in aqueous humor compared with total IgG in aqueous humor divided by anti–*Toxoplasma*-specific

IgG in serum compared with total IgG in serum. A value of ≥2 or ≥ 3 depending on expert opinion is considered diagnostic of ocular toxoplasmosis. Vitreous fluid sampling, despite the greater risk of damage to the eye and retina, can be indicated when significant vitreal inflammation is observed, retinal lesions are difficult to visualize, or the patient is not responding to anti-*Toxoplasma* therapy. For vitreal samples, detection of the parasite by DNA amplification (PCR) is preferred.

Diagnosis in Immunocompromised Children

Clinicians should establish whether immunocompromised patients, or patients about to become so, are at risk of reactivating latent *T. gondii* infection (*Toxoplasma* IgG seropositive) or acquiring primary infection through the oral route or from a transplanted organ (*Toxoplasma* IgG seronegative). All patients whose cell-mediated immunity will be significantly compromised should be tested ahead of time for anti-*Toxoplasma* IgG and IgM antibodies (e.g., before transplantation). Serologic testing following transplantation is unreliable; in the posttransplant period, serologic results in previously seropositive individuals can be negative, can be unchanged, or can rise without clinical relevance.

Establishing that an immunocompromised patient is chronically infected with *T. gondii* (*Toxoplasma* IgG positive and IgM negative) also facilitates the decision for anti-*Toxoplasma* prophylaxis. *T. gondii*–seropositive patients with AIDS, patients who receive allogeneic HSCTs, or patients who receive drugs that target T- or B-lymphocyte immune responses should be followed closely and offered anti-*Toxoplasma* prophylaxis or preemptive therapy (should they become *Toxoplasma* PCR positive). Recipients of solid-organ transplants and the organ donors should be tested before transplantation procedures; donor-positive, recipient-negative patients are at high risk of developing life-threatening toxoplasmosis.

Methods of choice to diagnose toxoplasmosis in immunocompromised patients (due to reactivation of latent infection or acutely acquired primary infection) are testing of body fluids by PCR, examination of biopsy tissue by hematoxylin/eosin, Wright-Giemsa or *T. gondii*-specific immunoperoxidase stains, and isolation of the parasite. Real-time PCR (RT-PCR) testing is the diagnostic test of choice for *Toxoplasma* encephalitis (on CSF), pneumonia (on bronchoalveolar lavage fluid), disseminated disease (peripheral blood or urine), and chorioretinitis (vitreous fluid). Visualization of tachyzoites in any body fluid or tissue or isolation from body fluids (reference laboratories) also is diagnostic of toxoplasmosis.

Treatment

Treatment requires the combination of 2 drugs known to be active against *T. gondii;* pyrimethamine is the most effective drug and always should be prescribed in conjunction with folinic acid to prevent bone marrow toxicity. Other effective drugs include sulfadiazine, clindamycin, atovaquone, and trimethoprim-sulfamethoxazole (TMP-SMX) (Tables 273.1 and 273.2).

[a]Preferred regimens: pyrimethamine plus sulfadiazine, and folinic acid or, alternatively, trimethoprim-sulfamethoxazole. (Supportive data for other regimens are limited.)

[b]Includes immunocompetent children with severe acute infection, particularly in the setting of myocarditis, myositis, hepatitis, pneumonia, brain or skin lesions, and lymphadenopathy accompanied by severe or persisting symptoms. Treatment also indicated for patients with active ocular disease caused by primary infection or reactivation. (For drug dosing for ocular toxoplasmosis, please see Table 273.1). For toxoplasmic encephalitis in HIV patients, treatment should be continued for 3–6 weeks (or more, for severely ill patients who did not achieve complete response), followed by suppressive therapy.

[c]Folinic acid is leucovorin; folic acid must not be used as a substitute for folinic acid.

Pregnant Women

Treatment of acute *Toxoplasma* infection during pregnancy is aimed at preventing fetal infection or treating the infected fetus (Fig. 273.4). If results of serologic testing suggest acquisition of the infection during the first 18 weeks of gestation or shortly before conception, maternal treatment with spiramycin is indicated[65] (see Table 273.1). Spiramycin is not available commercially in the US. However, it can be obtained at no cost (drug compassionately provided by Sanofi-Aventis) and after consultation with the PAMF-TSL (650-853-4828), through the National Collaborative Treatment Trial Study (NCCTS) (773-834-4152), or through the FDA (301-796-1600). Therapy should be continued throughout pregnancy even if results of AF PCR obtained at ≥18 weeks of gestation are negative. If fetal infection is confirmed at ≥18 weeks, treatment with pyrimethamine, sulfadiazine, and folinic acid is recommended because of the high transmission rates after 18 weeks of gestation. If the patient already is receiving spiramycin, combination therapy should replace spiramycin. In some centers in Europe, the change to combination therapy takes place as early as weeks 14 to 16. Pyrimethamine should be avoided earlier in gestation because it is potentially teratogenic. Combination therapy also is recommended when results of AF PCR for *T. gondii* DNA are positive or when fetal ultrasound changes are highly suggestive of congenital toxoplasmosis.

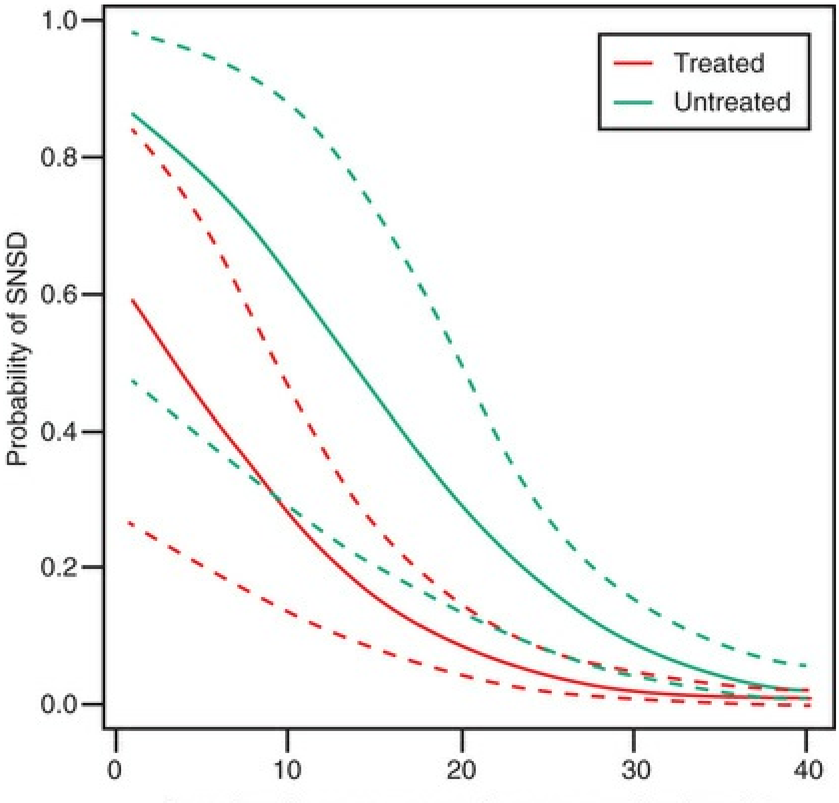

FIGURE 273.4 Probability of severe neurologic sequelae or death (SNSD) according to maternal treatment status (imputed gestational age at seroconversion [*solid lines*] and 95% Bayesian credible limits [*dashed lines*]). (From Cortina-Borja M, Tan HK, Wallon M, et al. Prenatal treatment for serious neurological sequelae of congenital toxoplasmosis: an observational prospective cohort study. Although no randomized clinical trials have been conducted on the efficacy of prenatal treatment, accumulated evidence from several observational cohort studies provides strong support for the benefit of prenatal screening and treatment in decreasing both the mother-to-child-transmission risk and the severity of congenital toxoplasmosis. The Systematic Review on Congenital Toxoplasmosis (SYROCOT)[44] revealed that when prenatal treatment was promptly initiated within 3 weeks of maternal seroconversion, the likelihood of mother-to-child-transmission was 52% lower, compared with delayed treatment initiation.[44] The lowest rates of mother-to-child-transmission have been observed in Germany,[49] where spiramycin is given until the 16th week of gestation in women with acute primary infection during pregnancy followed by at least 4 weeks of pyrimethamine-sulfadiazine plus folinic acid, independently of the fetal infection status (4.8% [33 cases in 685 pregnant women]) (The treatment for the rest of the pregnancy was determined based on the AF PCR and fetal ultrasound results.). Investigators from France reported that when monthly prenatal screening became mandatory in 1992, the delay between infection and treatment was reduced, and the risk of fetal infection decreased, for example, from 59.6% to 46.6% ($P = 0.038$) for maternal infections at the 26th week of gestation.[39] When AF PCR testing was introduced in France in 1995, earlier treatment of infected fetuses with the combination of pyrimethamine and sulfadiazine ensued, and the risk of developing clinical signs in children who were followed up for 3 years dropped significantly (odds ratio, 0.59; 95% confidence interval: 0.4–0.89; $P = 0.012$).[39] In Austria the risk of mother-to-child-transmission was sixfold lower in women who received prenatal treatment compared with untreated women, taking into account the gestational age at maternal infection (9% [87 cases in 1007 women] vs. 51% [32 cases in 63 women]).[47] An analysis of 293 infants from 14 European centers showed that antepartum treatment of toxoplasmosis was associated with 76% lower odds of severe neurologic sequelae or death.[50] In summary, early diagnosis and treatment of acute *Toxoplasma* infection should be offered to each pregnant woman.

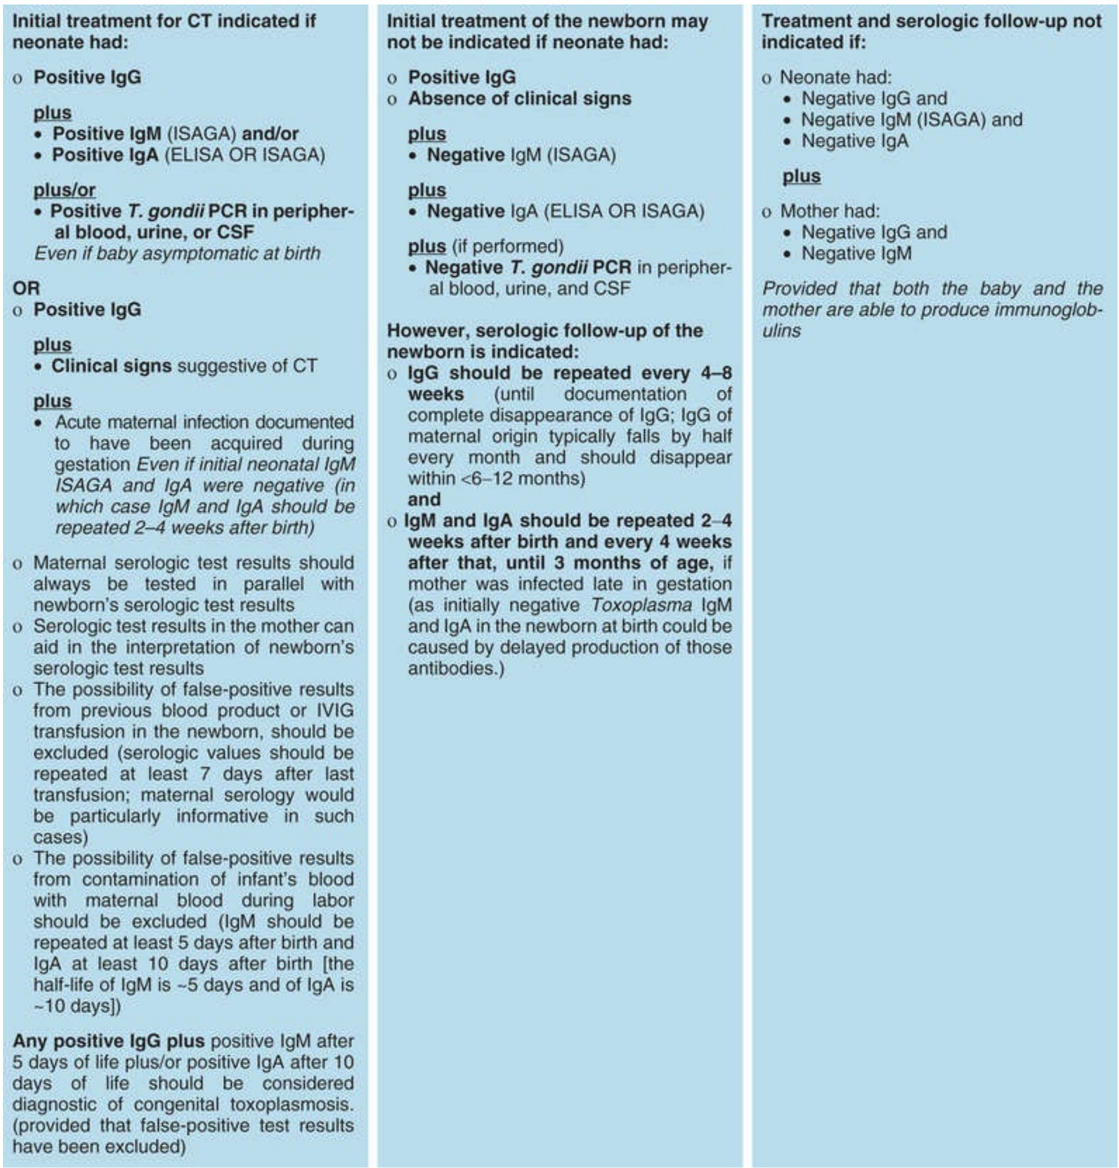
Neonates

The approach to treatment and follow-up based on diagnostic test results is shown in Fig. 273.5. Pyrimethamine, sulfadiazine, and folinic acid therapy is recommended in infants <1 year of age when congenital toxoplasmosis is highly suspected or confirmed[2] (see Table 273.1). Data on the effectiveness of other regimens such as TMP-SMX or pyrimethamine plus clindamycin plus folinic acid in this context are insufficient.



Initial treatment for CT indicated if neonate had:

- **Positive IgG**

  plus
  - **Positive IgM** (ISAGA) **and/or**
  - **Positive IgA** (ELISA OR ISAGA)

  plus/or
  - **Positive *T. gondii* PCR in peripheral blood, urine, or CSF**

  Even if baby asymptomatic at birth

OR

- **Positive IgG**

  plus
  - **Clinical signs** suggestive of CT

  plus
  - Acute maternal infection documented to have been acquired during gestation *Even if initial neonatal IgM ISAGA and IgA were negative (in which case IgM and IgA should be repeated 2–4 weeks after birth)*

- Maternal serologic test results should always be tested in parallel with newborn's serologic test results
- Serologic test results in the mother can aid in the interpretation of newborn's serologic test results
- The possibility of false-positive results from previous blood product or IVIG transfusion in the newborn, should be excluded (serologic values should be repeated at least 7 days after last transfusion; maternal serology would be particularly informative in such cases)
- The possibility of false-positive results from contamination of infant's blood with maternal blood during labor should be excluded (IgM should be repeated at least 5 days after birth and IgA at least 10 days after birth [the half-life of IgM is ~5 days and of IgA is ~10 days])

Any positive IgG plus positive IgM after 5 days of life plus/or positive IgA after 10 days of life should be considered diagnostic of congenital toxoplasmosis. (provided that false-positive test results have been excluded)

Initial treatment of the newborn may not be indicated if neonate had:

- **Positive IgG**
- **Absence of clinical signs**

  plus
  - **Negative** IgM (ISAGA)

  plus
  - **Negative** IgA (ELISA OR ISAGA)

  plus (if performed)
  - **Negative *T. gondii* PCR** in peripheral blood, urine, and CSF

However, serologic follow-up of the newborn is indicated:

- **IgG should be repeated every 4–8 weeks** (until documentation of complete disappearance of IgG; IgG of maternal origin typically falls by half every month and should disappear within <6–12 months)

  and
- **IgM and IgA should be repeated 2–4 weeks after birth and every 4 weeks after that, until 3 months of age,** if mother was infected late in gestation (as initially negative *Toxoplasma* IgM and IgA in the newborn at birth could be caused by delayed production of those antibodies.)

Treatment and serologic follow-up not indicated if:

- Neonate had:
  - Negative IgG and
  - Negative IgM (ISAGA) and
  - Negative IgA

  plus
- Mother had:
  - Negative IgG and
  - Negative IgM

Provided that both the baby and the mother are able to produce immunoglobulins

FIGURE 273.5 Management algorithm for infants with suspected or confirmed congenital toxoplasmosis (CT). CSF, cerebrospinal fluid; Ig, immunoglobulin; IVIG, intravenous immune globulin; ISAGA, immunosorbent agglutination assay; PCR, polymerase chain reaction.

Immunocompetent and Immunocompromised Children

Treatment is indicated for immunocompetent children with severe acute *Toxoplasma* infection who have clinically significant syndromes including myocarditis, myositis, hepatitis, pneumonia, brain lesions, or skin lesions[66] (see Table 273.2). Although *Toxoplasma* lymphadenitis usually is considered a self-limited disease, treatment is indicated in patients who have severe or persisting symptoms. Treatment also is indicated in patients with active ocular disease (see Table 273.1).

The optimal duration of treatment for chorioretinitis in children has not been studied. Based on experience in adults, anti-*Toxoplasma* treatment usually is continued for at least 1 to 2 weeks after resolution of clinical signs and symptoms of acute chorioretinitis and for approximately 4 to 6 weeks total, whichever is longer.[67,68] Although acute eye disease often resolves within 10 to 14 days after initiation of treatment, some cases resolve more slowly. Longer treatment durations with pyrimethamine plus sulfadiazine have been proposed, for up to 3 months in children[53,69] and 4 months in adults.[70] Close ophthalmologic follow-up every 2 to 3 weeks is necessary in all cases of active toxoplasmic chorioretinitis to determine response and optimal duration of treatment. The drug regimen of choice is pyrimethamine plus sulfadiazine plus folinic acid. The use of alternative regimens such as TMP-SMX or a combination of pyrimethamine, clindamycin, and folinic acid (see Table 273.2) in these patients is supported by adult trials; such data are not available in children.

Prevention

Primary Infection

Seronegative pregnant women and immunocompromised patients should be educated on the known risks factors for the acquisition of *T. gondii* and avoidance strategies (Table 273.3). All pregnant women and immunocompromised patients should be screened for *Toxoplasma* IgG and IgM antibodies regardless of clinical or epidemiologic history. Seronegative pregnant women should be tested serially during gestation to detect seroconversion at the earliest time possible. Universal screening for *T. gondii* infection during pregnancy and monthly monitoring of seronegative women (as currently done in France) is not mandatory currently in the US. However, a decision analysis in the US showed that the implementation of a universal monthly antepartum screening program, including antepartum treatment, fetal ultrasound scans, AF PCR, and infant follow-up and treatment, was a cost-saving strategy, (with results remaining robust in several sensitivity analyses).[71] The role of prenatal screening and treatment for congenital toxoplasmosis in the US may need reevaluation, considering the abundance of favorable observational studies.[18,39,44,47–50]

TABLE 273.3

Recommendations for the Primary Prevention of *Toxoplasma gondii* Infection in Seronegative People[a]

Vehicle of Transmission	Recommendation
Meat and other edibles	Meat should not be "pink" in the center Cook meat thoroughly up to ≥63°C (145°F) for whole cut meat (excluding poultry); up to ≥71°C (160°F) for ground meat (excluding poultry), and up to ≥74°C (165°F) for all poultry (whole cuts and ground)[75]
	Freezing and thawing can kill *T. gondii* tissue cysts; freeze meat to −20°C for at least 24 hr
	Infected meat that has been smoked, cured in brine, or dried still can be infectious
	Wash hands carefully after contact with raw meat
	Avoid mucous membrane contact when handling raw meat
	While wearing gloves, wash kitchen surfaces and utensils that have come in contact with raw meat
	Abstain from skinning or butchering animals without wearing gloves
	Avoid drinking unpasteurized goat milk
	Avoid eating raw oysters, clams, or mussels
	Carefully wash fruits, vegetables, or any organic edibles
Untreated water	Refrain from drinking untreated water including that from wells or reservoirs that have not been secured from potential contamination by feces from wild or domestic cats
Cat feces and soil exposure[75]	**Pregnant women** Avoid contact with soil potentially contaminated with cat feces, especially handling of cat litter or gardening
	Wearing gloves is recommended during gardening or any contact with soil or sand because it could be contaminated with cat feces that contain *T. gondii* oocysts; if these activities cannot be avoided, wash hands with soap after gardening or contact with soil or sand **Nonpregnant people** Wash hands with soap after gardening or contact with soil or sand Change cat litter box daily (if own a cat); *T. gondii* becomes infectious after 5

	days from shedding in cat feces Keep outdoor sandboxes covered Keep cats indoor Do not feed cats raw or undercooked meats

[a] Up to 50% of people can become infected with *T. gondii* even without recalling behaviors associated with the acute infection.[30,31]

Recommendations for prevention of acute infections, particularly in seronegative pregnant women and immunocompromised children, are summarized in Table 273.3.

Seronegative recipients of noncardiac solid-organ transplants who receive an allograft from a seropositive donor should receive TMP-SMX prophylaxis for at least 6 months. Cardiac transplant recipients can also be given pyrimethamine prophylaxis for at least 6 weeks. These regimens have been reported to be effective in the prevention of primary infection in newly immunosuppressed patients at risk for toxoplasmosis.

Reactivation of Latent Infection

TMP-SMX and atovaquone have been used to prevent reactivation of latent infection in immunosuppressed adults. Dapsone plus pyrimethamine, and pyrimethamine plus sulfadiazine, also have been reported to be effective, but use of these drugs is limited by potential hematologic toxicity. Prophylaxis against reactivation of latent infection has been successful in patients infected with *T. gondii* who have AIDS and $CD4^+$ T lymphocyte counts <200 cells/mm^3. *Toxoplasma*-seropositive recipients of an allogeneic HSCT who develop graft-versus-host disease represent a unique challenge. Reactivation of *T. gondii* in immunocompromised persons can manifest as nonspecific illness (e.g., fever or pneumonia) yet be life-threatening; disease often is not recognized. Atovaquone prophylaxis has been proposed as an alternative regimen in these patients given the potential toxicity of TMP-SMX. Some investigators have proposed a preemptive strategy in which *Toxoplasma*-seropositive patients who receive an allogeneic HSCT and develop graft-versus-host disease are monitored routinely (e.g., weekly for the first 100 days) with blood *T. gondii* PCR. Patients with positive PCR results are given TMP-SMX or atovaquone preemptively. Discontinuation of prophylaxis against *Toxoplasma* encephalitis has proved safe in patients with AIDS who are receiving combination antiretroviral therapy, who have $CD4^+$ T-lymphocyte counts ≥200 cells/mm^3, and whose viral load has been undetectable for at least 6 months.

In patients with *Toxoplasma* chorioretinitis who experience frequent recurrences (e.g., >2 episodes/year), oral TMP-SMX for at least 12 months has been reported to be effective in the prevention of relapses in adults.[72,73] Eye disease recurrences vary according to whether the patient received antepartum treatment or postnatal treatment or both.[16,54,74]

Key Points

Toxoplasma gondii

Epidemiology

- *Toxoplasma* infection occurs by ingestion of viable tissue cysts in meat or oocysts in food or water.
- Congenital infection occurs almost exclusively when the mother becomes acutely infected during gestation (or within 3 months before conception).
- Chorioretinitis occurs after congenital infection, with reactivation of congenital infection, or with postnatally acquired acute infection.
- Organ transplant recipients can acquire the infection from the transplanted organ or can have reactivation of latent infection following immunosuppression.

Clinical Features

- *Congenital toxoplasmosis findings in the fetus:* asymptomatic *or* intrauterine growth retardation, hydrocephalus, intracranial calcifications, intrahepatic calcifications, echogenic bowel, hydrops fetalis, pericardial/pleural effusions, fetal death
- *Congenital toxoplasmosis findings in the newborn/infant:* asymptomatic *or* chorioretinitis, macular or peripheral retinal lesions, strabismus, visual impairment, hydrocephalus, macrocephaly or microcephaly, intracranial or intrahepatic

calcifications, preterm birth, psychomotor or mental retardation, abnormal muscle tone, seizures, nerve palsies, hepatosplenomegaly, jaundice, rash, sensorineural hearing loss, rarely sepsis-like illness, cerebrospinal fluid (CSF) abnormalities (pleocytosis, elevated protein, eosinophilia, hypoglycorrhachia), thrombocytopenia, anemia, hepatitis

- *Postnatally acquired acute infections in immunocompetent children:* asymptomatic *or* flu-like or mononucleosis-like illness, lymphadenopathy; occasionally severe disease

- *Toxoplasmosis in immunocompromised children* (reactivation of past infection): severe disseminated disease with multiorgan involvement; sepsis-like illness; fever; pneumonitis; myocarditis; hepatitis; encephalitis; seizures; myositis

- Toxoplasmosis should be in the differential diagnosis when compatible clinical signs and symptoms are present, independent of risk factors (50% of acutely infected patients do not recall known risk factors).

Diagnosis

- Evaluation for suspected congenital toxoplasmosis in the fetus: maternal serology; amniotic fluid *T. gondii* PCR, and fetal ultrasound

- Evaluation for suspected congenital toxoplasmosis in the newborn:

- Maternal serology and anti–*Toxoplasma*-specific immunoglobulin G (IgG), plus IgM (by immunosorbent agglutination assay, [ISAGA]) plus IgA (by enzyme-linked immunosorbent assay [ELISA] or ISAGA)

- *Toxoplasma* polymerase chain reaction in CSF, peripheral blood, and urine

- Testing of infants with suspected congenital toxoplasmosis should be performed at a reference laboratory because of the availability of the highly sensitive IgM-ISAGA test and PCR testing of blood/CSF and urine.

- Previous transfusion of blood products or IGIV may cause false-positive results.

- CSF analysis, complete blood count, and liver function tests

- Detailed pediatric, neurologic, and ophthalmologic evaluation (ideally by retinal specialist)

- Head computed tomography or head MRI or head ultrasound; abdominal ultrasound, and auditory brainstem responses

- Beyond the neonatal period, serologic assays can distinguish acute from chronic infection.

- Positive *Toxoplasma* IgM results at commercial laboratories should be confirmed at a reference laboratory (where comprehensive panel of tests are offered according to clinical situations).

- *In transplant recipients* diagnosis of acute *Toxoplasma* infection relies on positive polymerase chain reaction results from peripheral blood, CSF, urine, or other body tissues or body fluids or histopathologic examination with immunoperoxidase staining. Pretransplant serologic findings in the donor and recipient can assist in the diagnosis. Serologic findings in the posttransplant period frequently are not helpful.

Treatment

- *Congenital toxoplasmosis:* pyrimethamine plus sulfadiazine plus folinic acid

- *Severe toxoplasmosis in immunocompetent or immunocompromised children*: pyrimethamine plus sulfadiazine plus folinic acid or alternatively, trimethoprim-sulfamethoxazole.

Prevention and Prophylaxis

- Avoid undercooked meat and food/water potentially contaminated with *T. gondii*–infected soil and contact with *T. gondii*–infected soil

- Severely immunocompromised children should receive anti-*Toxoplasma* prophylaxis according to their *T. gondii* serologic status.

- Posttransplant recipients should receive prophylaxis according to the *T. gondii* pretransplant serologic status in the donor and recipient.

Trichomonas vaginalis

Elissa Meites, Kimberly A. Workowski

Trichomonas vaginalis can infect both men and women and is recognized as the most common nonviral sexually transmitted infection in the world.[1]

Description of the Pathogen

T. vaginalis, a flagellated protozoan parasite, was first described in 1836 by French physician Alfred François Donné, who observed these "animalculi" in vaginal fluid under a light microscope.[2] *T. vaginalis* eukaryotic parasites are typically oval or fusiform, 7 to 32 µm long, and 5 to 12 µm wide (Fig. 274.1).[3] Each has 4 anterior flagella that appear to arise from a single stalk, a central axostyle, and an undulating membrane that extends across the organism. The microbe contains a large anterior nucleus and well-developed Golgi bodies. The organism generates metabolic energy in membrane-bound chromatic granules called hydrogenosomes.[3] All areas of the cell surface are capable of phagocytosis and can ingest bacteria, leukocytes, and other particles. *T. vaginalis* is facultatively anaerobic, uses a variety of carbohydrate sources, has limited biosynthetic capabilities, and grows in various liquid and semisolid media or in cell culture, especially in low-pH environments (i.e., pH 4.9–7.5).[3,4] The organism reproduces by binary fission every 4 to 6 hours.

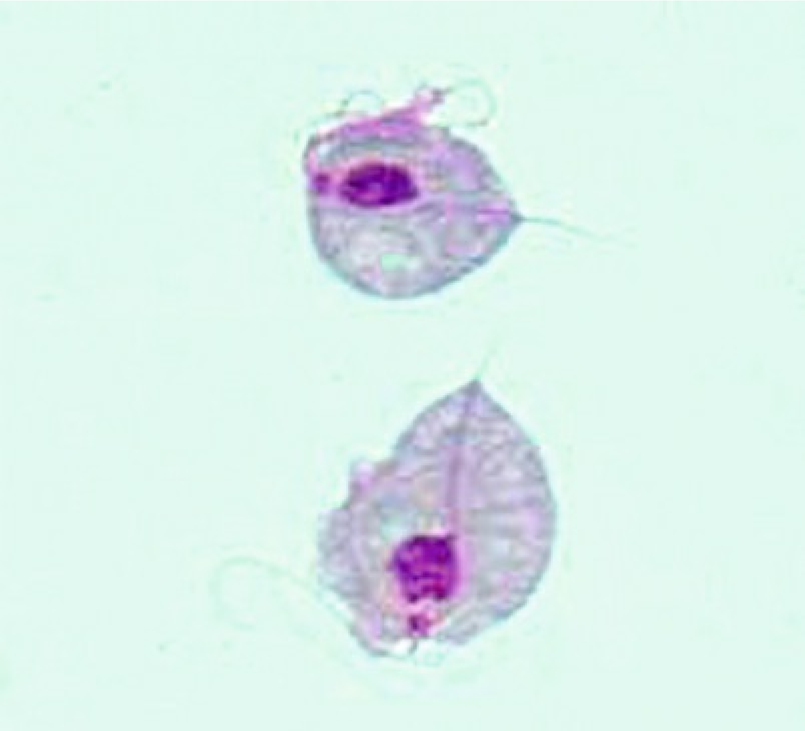

FIGURE 274.1 **Two trophozoites of *Trichomonas vaginalis* obtained from in vitro culture (Giemsa stain).** (From Centers for Disease Control and Prevention.)

T. vaginalis parasites exist only in trophozoite form, and humans are the only hosts.[3] Parasites readily attach to mucous membranes by adhesion proteins and can damage epithelial cells by direct contact.[5,6] Epithelial damage also can be caused by contact-independent mechanisms, including soluble and membrane-associated enzymes associated with phospholipase A activity, which can lyse nucleated cells in vitro and contribute to tissue damage and inflammation.[7–9] *T. vaginalis* can induce both humoral and cell-mediated immune inflammatory responses, but these responses are not protective because repeated and persistent infections can occur.[3]

Epidemiology

T. vaginalis infection is the most prevalent nonviral sexually transmitted infection. It causes an estimated 3.7 million infections annually in the United States, including 2.3 million infections among women and 1.4 million infections among men.[10] Neither trichomoniasis nor *T. vaginalis* infection is a nationally notifiable condition or reportable in any US state, and prevalence estimates are based on nationally representative studies. Among adolescents in school grades 7 to 12, an estimated 2.8% of girls and 1.7% of boys are infected with *T. vaginalis*.[11]

Health disparities by race or ethnicity are substantial. In a nationally representative study in the US, the prevalence of infection among non-Hispanic black women was 13%, significantly higher than the 1.8% prevalence among Mexican-American women and 1.3% among non-Hispanic white women.[12] Prevalence also increases with age, peaking at more than 11% among women ≥40 years of age.[12,13]

High-risk groups include incarcerated populations, with prevalences of 9% to 32% among incarcerated women and 2% to 9% among incarcerated men.[13–20] The prevalence of infection is also high among sexually transmitted disease clinic patients, at 17% of men and 26% of women tested.[21,22] Among women using drugs, the prevalence of *T. vaginalis* infection ranges from 13% to 38%.[23–25]

Transmission results almost exclusively from sexual contact during penile-vaginal sexual intercourse. *T. vaginalis* does not commonly cause oral or rectal infections.[26] Perinatal transmission of trichomoniasis can occur; the presence of *T. vaginalis* in a child beyond the perinatal period is considered suggestive of sexual abuse.[27,28]

Clinical Manifestations

Approximately 70% to 85% of *T. vaginalis* infections are asymptomatic.[12,29] Initial symptoms, when present, may develop within 5 to 28 days after infection. Untreated infections can last for months to years.[30,31]

Women

Women can develop signs and symptoms including vaginal discharge, vulvovaginal irritation, dysuria, and dyspareunia. Lower abdominal pain is less common. Associated vulvar and vaginal erythema with copious frothy discharge pooling in the posterior vaginal fornix can be present. Punctate hemorrhagic lesions in the genital epithelium can result in colpitis macularis ("strawberry cervix"), a finding specific for trichomoniasis. Discharge ranges in appearance but can be yellow green, malodorous, and diffuse.[32,33] The differential diagnosis of vaginal discharge can include bacterial vaginosis, candidal vulvovaginitis, and cervicitis related to other sexually transmitted diseases such as *Chlamydia* infection or gonorrhea. *T. vaginalis* infection is associated with preterm delivery as well as an increased risk of human immunodeficiency virus (HIV) infection.[34–38]

Men

Men may develop symptoms of urethritis, epididymitis, or prostatitis. Urethral discharge is common, and dysuria and pruritus can occur. *T. vaginalis* is responsible for 1% to 15% of cases of nongonococcal urethritis in men.[11,21,39,40] *T. vaginalis* urethritis cannot be distinguished clinically from nongonococcal urethritis caused by other pathogens, such as *Mycoplasma genitalium* or *Chlamydia trachomatis*. In areas where *T. vaginalis* is highly prevalent, men who have sex with women and have persistent or recurrent urethritis should be presumptively treated.[41]

Children

A few cases of trichomoniasis have been reported in premature newborns infected during vaginal deliveries.[42–44] Neonatal symptoms have included self-limited vaginal discharge, urinary tract infection, or respiratory tract symptoms. Such infections are self-limited and are expected to resolve within weeks.

Laboratory Findings and Diagnostic Tests

Although trichomoniasis is a clinical diagnosis, various laboratory assays are used to detect the presence of *T. vaginalis* parasites in vaginal or endocervical fluid from women, semen or urethral swabs from men, or urine specimens. Traditionally, screening and testing for this parasite have focused on women, and newer molecular tests may not be approved by the US Food and Drug Administration for use in male specimens given limited available data.

The most common test is microscopic evaluation of genital secretions (“wet mount”). This test is often performed by swabbing the anterior and posterior vaginal fornices, agitating the swab in 1 mL of saline solution, and examining a drop of the fluid on a microscope slide. Characteristic twitching of motile parasites can be seen under low (×100) or medium (×400) magnification. However, nonmotile parasites can be overlooked or mistaken for similarly sized leukocytes. Sensitivity of wet mount is poor (51%− 65%) and operator dependent, and it declines rapidly as microscopy is delayed.[45–48] To increase sensitivity, various algorithms have been suggested in which initial negative wet mount results are followed by a more highly sensitive test.[47]

Culture has a sensitivity of 75% to 96% and a specificity of up to 100%.[46,47] A commercially available culture system (InPouch TV, BioMed Diagnostics, White City, Ore) appears to be comparable to traditional Diamond media while permitting easier transport and storage.

Sensitive same-day rapid tests can be performed at the point of care. The OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Framingham, Mass) is a Clinical Laboratory Improvement Amendments (CLIA)–waived immunochromatographic dipstick (sensitivity, 82%–95%; specificity, 97%−100%) with results in 10 minutes.[46,49–51] The Affirm VP III (BD Diagnostics, Sparks, Md) is a nucleic acid probe-hybridization test that evaluates for 3 causes of vaginitis: *Gardnerella vaginalis*, *Candida albicans,* and *T. vaginalis* (sensitivity of ≥63% specificity of 99.9%) with results in 45 minutes.[52,53]

Highly sensitive nucleic acid amplification tests that are now cleared by the Food and Drug Administration include the BD Probe Tec TV Q^x Amplified DNA assay (BD Diagnostics) and the APTIMA *Trichomonas vaginalis* assay (Hologic, San Diego, Calif) (sensitivity, 95.2%−100%; specificity, 95.3%−100.0%).[46,52,54,55]

Papanicolaou (Pap) smears are neither sensitive nor specific tests for trichomoniasis, although *T. vaginalis* parasites can be incidental findings.[48]

Treatment

The only medications approved in the US for treating trichomoniasis are metronidazole and tinidazole, both 5-nitroimidazole antibiotic medications. Sexually transmitted disease treatment guidelines from the Centers for Disease Control and Prevention recommend therapy with a single 2-g dose of either metronidazole or tinidazole orally; additional doses or longer treatment courses have been used successfully in patients with recurrent or persistent infections.[41] Randomized controlled trials demonstrated that tinidazole had efficacy equal to or superior to that of metronidazole, with cure rates of 86% to 100%.[56–60] In case of medication allergy, desensitization according to a published regimen can be considered.[61] Treatment of all sexual partners prevents recurrences in the index case, reduces transmission, and prevents new cases in the community.[41]

Most strains of *T. vaginalis* are susceptible to metronidazole, although antimicrobial resistance is an emerging issue. Among specimens from women diagnosed with trichomoniasis at sexually transmitted disease clinics in 6 cities, 4.3% exhibited low-level metronidazole resistance in vitro, and none demonstrated tinidazole resistance.[62] However, in a study of *T. vaginalis* isolates from 175 women with persistent trichomoniasis whose clinicians consulted the Centers for Disease Control and Prevention for susceptibility testing after standard therapy failed at least twice, 115 (66%) demonstrated some level of metronidazole resistance.[63] Treatment failure resulting from antimicrobial-resistant *T. vaginalis* should be distinguished from the possibility of reinfection from an untreated sexual partner.[41]

Special Considerations

Pregnancy and Lactation

Maternal *T. vaginalis* infection is associated with adverse pregnancy outcomes, including premature rupture of membranes, preterm delivery, and delivery of a low birth weight infant.[36,64] However, no clear evidence indicates that metronidazole treatment results in a reduction in perinatal morbidity.[37,65] For asymptomatic women, screening can be considered at the discretion of the treating clinician. Symptomatic pregnant women should be tested for *T. vaginalis* infection and considered for treatment with metronidazole.[41]

For lactating women, some clinicians recommend deferring breastfeeding for 12 to 24 hours following a 2-g dose of metronidazole and for 72 hours following a 2-g dose of tinidazole.[41,66–68]

Human Immunodeficiency Virus Infection

T. vaginalis infection is associated with both acquisition and transmission of HIV.[34,35,69–72] Up to 53% of women with HIV infection have been found to be coinfected with *T. vaginalis*; prevalence among HIV-infected men is unknown.[25,73] Women infected with both HIV and *T. vaginalis* should receive metronidazole 500-mg orally twice daily for 7 days because this regimen significantly improved cure rates in a randomized trial.[74]

Prevention

Treatment of all sexual partners can prevent recurrences, reduce transmission, and prevent new cases of trichomoniasis. Among sexually active people, the risk of trichomoniasis and other sexually transmitted infections can be reduced by using condoms consistently and correctly.[75] Periodic presumptive nitroimidazole treatment for people at high risk such as sex workers can effectively reduce the occurrence of trichomoniasis.[76,77] Male circumcision may reduce the risk of *T. vaginalis* infections for circumcised men and their female sexual partners.[78,79] Data are needed on effective intervention strategies to reduce associated health disparities.

Key Points

Trichomonas Vaginalis Infections

Epidemiology

- *Trichomonas vaginalis* is the most prevalent nonviral sexually transmitted infection, causing 3.7 million infections annually among men and women in the United States.

- Among adolescents, an estimated 2.8% of girls and 1.7% of boys are infected.

- Prevalence of infection increases with age, and the infection affects a disproportionately high percentage of black women.

- High-risk groups include incarcerated populations and sexually transmitted disease clinic patients.

- *T. vaginalis* infection is associated with preterm delivery and an increased risk of human immunodeficiency virus (HIV) infection.

Clinical Features

- 70% to 85% of *T. vaginalis* infections are asymptomatic.

- Women can develop vaginal discharge, vulvovaginal irritation, dysuria, and dyspareunia; punctate hemorrhagic lesions can cause colpitis macularis (“strawberry cervix”), which is specific for trichomoniasis.

- Men can develop symptoms of urethritis, epididymitis, or prostatitis.

- Neonates can develop self-limited vaginal discharge, urinary tract infection, or respiratory tract symptoms.

Diagnosis

- Traditional diagnostic tests: wet mount microscopic evaluation (poor sensitivity) or culture

- Same-day point-of-care tests: OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Framingham, Mass), Affirm VP III (BD Diagnostics, Sparks, Md)

- Nucleic acid amplification tests (high sensitivity): BD Probe Tec TV Q^x Amplified DNA assay (BD Diagnostics), APTIMA *Trichomonas vaginalis* assay (Hologic, San Diego, Calif)

Treatment

- A single 2-g dose of either metronidazole or tinidazole orally usually is sufficient for cure.

- HIV-infected patients should receive a 500-mg dose of metronidazole twice daily for 7 days to improve cure rates.

- Antimicrobial resistance is an emerging concern given lack of treatment alternatives.

Prevention

- All sex partners should be treated to prevent recurrent and new cases.

- Risk of sexually transmitted infections can be reduced by abstaining from sex or using condoms.

Trypanosoma Species (Trypanosomiasis)

Amelia B. Thompson, Andres F. Camacho-Gonzalez

Organisms of the genus *Trypanosoma* are flagellated protozoan parasites that inhabit the blood and tissue of a wide variety of vertebrate hosts, including birds, reptiles, and mammals. The name is derived from the Greek, *trypano* (meaning auger, a helical shaped tool) and *soma* (meaning body). The trypanosomes that infect humans in Africa *(T. brucei)* are transmitted by the bite of *Glossina* flies, whereas human trypanosomiasis in the Americas *(T. cruzi)* is transmitted by feces of triatomid insects.[1–3] In combination, African trypanosomiasis and American trypanosomiasis cause significant morbidity and death throughout the world, thus calling for expansion of prevention efforts, with improved diagnostic methods and treatment strategies.

Human African Trypanosomiasis

Human African trypanosomiasis, also known as sleeping sickness, is a vector-borne parasitic disease caused by 2 subspecies of the *Trypanosoma brucei* complex: *Trypanosoma brucei gambiense (T. b. gambiense)* and *Trypanosoma brucei rhodesiense (T. b. rhodesiense)*.[1–8] They are both transmitted by male and female *Glossina* flies (“tsetse flies”), but they cause entities with significant epidemiologic and treatment differences.[1,9]

Description of the Pathogen

The African trypanosomes are extracellular hemoflagellate parasites that are members of the Trypanosomatidae family, genus *Trypanosoma,* and subgenus *Trypanozoon.*[1] The life cycle includes both insect vector and mammalian host. After inoculation of infective metacyclic trypomastigotes into subcutaneous tissue by an infected tsetse fly, trypanosomes are converted to the pleomorphic bloodstream trypomastigotes, which are infective for the tsetse fly (Fig. 275.1). In the vertebrate host, African *Trypanosoma* organisms always occur in the trypomastigote form, where they live and multiply in blood, cerebrospinal fluid (CSF), interstitial space of the lymph nodes, spleen, and brain. The tsetse fly ingests bloodstream forms when taking a blood meal from an infected animal. Procyclic trypomastigotes eventually migrate through the fly's esophagus toward the hypopharynx in the proboscis and into the salivary glands. In the salivary glands, the procyclic trypomastigotes transform into epimastigotes, attach to the epithelium, and finally become infective metacyclic trypomastigotes that are inoculated into the vertebrate host during a new blood meal (Fig. 275.2).[1,4]

Epidemiology

T. b. gambiense occurs in West and Central Africa and accounts for more than 98% of all cases of human African trypanosomiasis. *T. b. rhodesiense* is found in East and south-central Africa.[5,6] The geographic gap between the 2 forms has been decreasing in Tanzania, the Democratic Republic of Congo, and Uganda.[1,7,8] This finding is of clinical significance because the laboratory differentiation between the 2 species is difficult, and treatment varies by species.[1] Estimates have shown that approximately 57 million people living over a geographic area of 1.4 million km^2 are at risk of *T. b. gambiense* infection, and 12.3 million people living over an area of 0.2 million km^2 are at risk of infection with *T. b. rhodesiense*.[8] Significant control efforts, including improvements in surveillance, vector and reservoir control, and wider accessibility to diagnostic methods and treatment, have resulted in a significant decline in the reported cases, with incident cases dropping to fewer than 10,000 for the first time in 2009 and reaching a record low of

6314 in 2013.[9]

Tsetse flies flourish at temperatures between 20°C and 30°C, in high humidity, and at an altitude lower than 1800 m. The development period of the parasite in the tsetse fly takes approximately 3 weeks; infection is lifelong (≤11 months) but is not passed to the fly's progeny. *Glossina palpalis* and *G. tachinoides,* which inhabit dense vegetation along river banks, are the most common vectors of *T. b. gambiense*, whereas *T. b. rhodesiense* is transmitted to humans by *G. morsitans* and less frequently by *G. swynnertoni* and *G. pallidipes,* which inhabit savannas and lake shores.[6] The main reservoir for *T. b. gambiense* is humans; however, animal reservoirs play important roles in human transmission of *T. b. rhodesiense,* with natural infections occurring in domestic animals, including cattle, sheep, and goats, and in some wild animals such as lions, hyenas, and several species of antelope.[6] The incubation period ranges from 5 days to a few weeks in *T. b. rhodesiense* infection and up to years in *T. b. gambiense* infection.[10] Humans primarily acquire *T. brucei* infections through the bite of infected tsetse flies. Rarely, humans can be infected transplacentally or by blood transfusion. The disease attacks all age groups and is equally frequent in female and male patients; however, children are infected rarely, mainly because of a decreased risk of exposure. The disease is invariably fatal if untreated.[1,6]

Pathogenesis and Pathology

After organisms are injected into the mammalian host with the saliva of the tsetse fly, they enter the lymphatics and then the bloodstream (see Fig. 275.2). Protective factors isolated from normal human plasma include trypanosome lytic factors 1 and 2 (TLF-1 and TLF-2), which destroy trypanosomes that are pathogenic in animals, but not *T. b. gambiense* and *T. b. rhodesiense,* as a result of acquired resistance mechanisms.[1] The TLFs have 2 components: apolipoprotein A1 (APOL1), which can form pores in lysosomes and elicit apoptotic pathways; and haptoglobin-related protein (HPR), which targets TLF-1 to the parasite. Together, APOL1 and HPR assemble into a single high-density lipoprotein to attack the parasite.[11–17]

Each subspecies has evolved and developed mechanisms to evade these protective responses. *T. b. rhodesiense* expresses a serum resistance-associated (SRA) gene that confers resistance to APOL1 by preventing its membrane insertion and enabling its degradation by proteases.[18–20] *T. b. gambiense* expresses a *T. b. gambiense*–specific glycoprotein (TgsGP) that prevents APOL1 insertion into endolysosomal membranes.[16,21,22] Inhibition of the *T. brucei* receptor for haptoglobin-hemoglobin also reduces the uptake of APOL1, thereby allowing for protease-mediated digestion of APOL1 in *T. b. gambiense*.[23] Both subspecies also use antigenic variation of the cell surface glycoproteins (variant surface glycoproteins) to avoid antibody-mediated clearance.[4,24]

Once these trypanosomes are able to avoid destruction by the immune system, they infect mammalian hosts and enter the lymphatic system where they cause lymph node enlargement with lymphocyte and mononuclear cell population expansion. Subsequently, the trypanosomes enter the bloodstream where they can disseminate to any organ (see Fig. 275.2). After a variable period, depending on the species, the organism enters the central nervous system (CNS) where it causes meningoencephalitis. The severity of symptoms is related directly to parasite burden. Histopathologic examination of the CNS reveals infiltration of plasma cells, macrophages, and lymphocytes, with perivascular proliferation of endothelial and neuroglia cells, severe cerebral edema, and punctate hemorrhage. Demyelination and neuronal damage have been observed and can extend deeply into white matter. Chronic meningoencephalitis can also occur. Vasculitis associated with increased permeability of the capillary vessels is considered to be the essential factor in pathogenesis and is suspected to be of immunopathogenic origin.[1,4,25]

Clinical Manifestations

Human African trypanosomiasis appears in 2 stages: the hemolymphatic stage and the meningoencephalitis stage. Infection caused by *T. b. rhodesiense* causes acute and severe disease with few CNS symptoms and death within weeks or months. *T. b. gambiense* infection is characterized by a milder, chronic, progressive course with involvement of the lymph nodes, CNS invasion, and a fatal outcome after several years.[4,25]

Within a few days, but up to 2 weeks after infection, an indurated, erythematous, painful, warm, circumscribed, rubbery lesion (trypanosomal chancre) can develop at the site of the tsetse fly bite. This lesion is seen in up to 20% of patients infected with *T. b. rhodesiense* and is much less common in *T. b. gambiense* infection. The lesion usually resolves within 3 weeks but with residual scarring and depigmentation.[1] The differential diagnosis includes cutaneous anthrax (in which marked swelling occurs around the eschar), syphilis, and African tick bite fever, caused by *Rickettsia africae* and *R. conorii*.

The early parasitemic phase of infection is accompanied by high fever, headache, and general malaise interspersed with relatively asymptomatic periods. As infection progresses, fever is intermittent, and a papular rash and generalized enlargement of lymph nodes occur, especially in the posterior cervical triangle (Winterbottom sign) and in the submaxillary, inguinal, and femoral regions. The nodes are discrete, soft, and nontender and contain abundant parasites.[26] The spleen and liver can be mildly enlarged. Over time, the patient develops dyspnea, chest pain, and loss of strength and becomes extremely emaciated.[25] Endocrine abnormalities include increased or decreased thyroid function, decreased sexual function, and, in women, amenorrhea. Arthralgia, weakness, and painful local edema of the hands, feet, and joints can be present. Deep hyperesthesia (Kerandel sign) is often reported in non-Africans; delayed, intense pain occurs when soft tissue is compressed.[26,27]

The most common laboratory abnormalities include hemolytic anemia, elevation of serum hepatic enzymes, coagulation abnormalities, thrombocytopenia, and hypocomplementemia. The sedimentation rate is markedly elevated.[4,28] The differential diagnosis during the first stage of the disease includes other causes of febrile illness occurring in the area, namely, malaria, typhoid fever, tuberculosis, brucellosis, syphilis, leptospirosis, hepatitis, borrelial relapsing fever, viral hemorrhagic fevers, and acute human immunodeficiency virus (HIV) infection.

In the second stage, sleep disturbance and neuropsychiatric disorders become more apparent. Meningoencephalitis can involve the spinal cord as well as the brain. The white matter of the brain shows pathognomonic cells called morula or Mott cells, which are plasma cells containing large concentrations of immunoglobulin M (IgM).[4] With CNS invasion, the chronic or sleeping sickness stage of infection is initiated.[25] Headache is severe, and irritability, personality and behavior changes, and gradual loss of cognitive function are common. Muscle spasms, ataxia, incoordination, tremor, alteration of reflexes, stiffness in the neck, papilledema, and flaccid paralysis occur. Psychiatric manifestations include hallucinations, delusional states, and overt psychoses. Choreiform or oscillatory movements of the arms, head, neck, and trunk are frequent.[4,6,29] Sleep disorders with diurnal somnolence, inappropriate episodes of sleeping, and nocturnal insomnia are prominent symptoms of the second stage.[4,25] Progressive somnolence and convulsions develop and lead to deep coma and death. Cardiac involvement can lead to congestive heart failure, pericardial effusion, and electrocardiographic changes.[30] Death results from meningitis, heart failure, or complications such as bacterial pneumonia. The differential diagnosis during the second stage of the disease includes other causes of chronic meningoencephalitis, especially tuberculosis, cryptococcal infection, and syphilis.

Congenital African trypanosomiasis, defined as the development of human African trypanosomiasis within the first 5 days of life,[31] has been described in a few case series.[31] In this form, progression to the second stage of the disease is faster. Transmission risk remains unknown.[31–33]

Diagnosis

The initial symptoms of human African trypanosomiasis are nonspecific. Therefore a combination of clinical signs in the correct epidemiologic setting should raise suspicion for this diagnosis.

Screening

In asymptomatic patients, screening can be performed for *T. b. gambiense* infection with a card agglutination test for trypanosomiasis (CATT), which uses a finger-prick drop of blood mixed on the card with a drop of reagent containing a freeze-dried trypanosomal antigen. If infection is present, agglutination occurs within 5 minutes.[6,26] This test can be performed in the field and has a sensitivity of 87% to 98% and a specificity of 93% to 95%.[26] False-negative results may occur in areas where the parasite does not express the specific antigen used in the test and as a result of a prozone phenomenon. Other serologic tests include immunofluorescent assay and enzyme immunoassay tests, which cannot be performed readily in the field.[34,35] No screening test is available for *T. b. rhodesiense* at this time.[1]

Symptomatic Disease

Diagnostic testing in a suspected case depends on visualizing the organism in blood, lymph node aspirate, bone marrow, or CSF by microscopic examination.[25] The miniature anion exchange centrifugation technique (mAECT) is the most sensitive technique available. In this assay, 350 μL of blood or CSF is obtained; the trypanosomes are isolated by anion exchange chromatography, concentrated by centrifugation, and then seen on microscopic examination. Fewer than 50 trypanosomes/mL of blood may be detected using this assay.[36] Additional techniques include the use of light-emitting diode fluorescence microscopy on lysed blood to visualize the trypanosomes and or loop-mediated isothermal amplification (LAMP), which uses a DNA amplification technique on a blood specimen.[37,38]

Older testing methods are less reliable because of the periodicity of parasitemia. Thick and thin Giemsa-stained smears of buffy coat preparations are more sensitive in *T. b. rhodesiense* infection, in which the degree of parasitemia is higher. This test has a lower limit of detection of approximately 5000 parasites/mL of blood. Concentration methods can increase the sensitivity. The microhematocrit centrifugation technique (Woo test), in which 6 to 8 sealed microhematocrit tubes are centrifuged and the buffy coat is examined using a long-distance objective lens for motile parasites, has a lower limit of detection of ~500 parasites/mL.[25] The quantitative buffy coat test, in which blood, ethylenediaminetetraacetic acid, and acridine orange stain are mixed and centrifuged, shows motile parasites with the use of fluorescence microscopy. Examination of wet preparations of lymph node aspirates has a sensitivity of 40% to 80%, similar to the sensitivity of blood examinations.[35,39] Several polymerase chain reaction tests for rapid detection of trypanosomes in human blood samples have been developed with sensitivities up to 100%.[6,40,41] However, molecular diagnostics have not been routinely used because of factors such as cost and the need for skilled personnel.[42]

Once the diagnosis of human African trypanosomiasis is made, CSF testing for staging purposes should be performed because the stage has important implications for therapy.[35] World Health Organization criteria for evidence of CNS infection are >5 leukocytes/mm^3 or visualization of trypanosomes. However, some clinicians use higher white blood cell count cutoffs such as >10 or >20 cells/mm^3. The presence of IgM in the CSF is an early and specific marker of CNS invasion.[25,26,43] A monoclonal antibody–based enzyme immunoassay for detection of *Trypanosoma* antigens in serum and CSF has high specificity (>99%) and sensitivity (*T. b. gambiense,* 95%; *T. b. rhodesiense,* 92%).[5]

Treatment

Few drugs are available to treat human African trypanosomiasis, with selection based mainly on the stage of disease and the specific pathogen. Early treatment is essential because the prognosis is poor once CNS involvement has occurred. In the absence of CNS disease, pentamidine and suramin are the drugs of choice.[1,6,44–46] These drugs do not cross the blood-brain barrier because of their poor lipophilic properties and are not considered when treating stage 2 disease.[45,47] Eflornithine alone or in combination with nifurtimox is used for treating stage 2 *T. b. gambiense* disease, and melarsoprol is used for stage 2 *T. b. rhodesiense* disease. Two newer drugs, fexnidazole and an oxaborole named SCYX-7158 have been developed, but they are still being tested in clinical trials.[46] Therapy is summarized in Table 275.1. Doses and side effects can be found in Chapter 296.

Prevention

In 2011, the World Health Organization Strategic and Technical Advisory Group on Neglected Tropical Diseases established an elimination goal for human African trypanosomiasis as a public health problem and created a roadmap toward this goal by 2020.[48,49] Routine preventive measures include avoiding known foci of tsetse infestation, avoiding endemic areas, wearing wrist- and ankle-length dark clothing, and use of insect repellents and mosquito bed nets. Clearing of vegetation around human settlements, limited destruction of game animals and potential wild reservoirs, prophylactic treatment of cattle and domestic animals, and spraying of insecticides have resulted in local eradication of the insect vector and a reduced incidence of human infection.[50] Refined vector control technologies may serve as potential, cost-effective strategies that could halt human African trypanosomiasis transmission.[51,52] Chemoprophylaxis is no longer available because of the poor risk-to-benefit ratio caused by adverse effects of the drugs.

American Trypanosomiasis

Chagas disease or American trypanosomiasis was discovered in 1909 by Dr. Carlos Chagas and is the result of infection by *T. cruzi*. Chagas disease is a systemic, lifelong infection that affects approximately 6 million people annually throughout the Americas.[2,53] This zoonotic infection is transmitted to humans by large, blood-sucking insects of the family Reduviidae. Three clinical stages are recognized in Chagas disease: a short acute stage; a long, clinically asymptomatic indeterminate stage; and a long-lasting chronic stage.[2,3] Large-scale vector control programs and screening of blood donors have reduced the incidence and prevalence of this disease.[54]

Description of the Pathogen

T. cruzi belongs to the genus *Trypanosoma,* subgenus *Schizotrypanum.* Members of this group develop in the lower gut and rectum of the triatomid vector (reduviid or kissing bug) (Fig. 275.3). The developmental cycle of *T. cruzi* includes 3 morphologic forms: amastigotes, epimastigotes, and trypomastigotes. The trypomastigote (Fig. 275.4) is found in the tissue and bloodstream (the only stage found in blood) of infected mammals and is responsible for the spread of infection from cell to cell and for transmission of the infection to the insect vector. The reduviid bug feeds on the vertebrate host and excretes the infectious forms (metacyclic trypomastigote) in its feces, which are rubbed or scratched into the bite wounds. The organisms can also enter the host through mucous membranes.

T. cruzi is classified into 6 discrete typing units based on genomic sequencing: TcI to TcVI.[55] TcI, TcII, TcV, and TcVI are most frequently isolated from domestic cycles and are responsible for most human infections. TcI strains have been more commonly associated with cardiac disease, whereas TcII to TcVI strains are more commonly associated with gastrointestinal disease.[56] A genetically divergent lineage with the potential to infect humans, TcBat, has been isolated across Panama, Brazil, and Colombia.[57–59]

Epidemiology

The World Health Organization has estimated that approximately 70 million people are at risk of acquiring *T. cruzi* infection.[53] However, since the 1990s, improvements in vector control programs and compulsory blood bank screening have significantly reduced the incidence of disease.[2,3] In 2010, more than 5.7 million people in 21 Latin American countries had a diagnosis of Chagas disease; 62% of these people were from Argentina, Brazil, and Mexico.[53] In endemic areas, the incidence of Chagas disease has decreased from 700,000 new cases/year to approximately

30,000/year. Mortality rates also have decreased from approximately 45,000 deaths/year to 12,500/year.[2,3,53] The country with the highest incidence rate is Bolivia, followed by Mexico and Colombia. Since the 1990s, *Triatoma infestans,* the primary vector species, has been eliminated in Uruguay, Chile, and Brazil, in addition to parts of Argentina and Paraguay.[2,3] Transmission routes include vector borne (most common), congenital acquisition (almost 9000 infections/year), bloodborne, organ derived, and oral transmission by contaminated fruit or sugar cane juice.[60–77]

In the United States, approximately 300,000 people are infected with *T. cruzi*, most of whom acquired the disease from endemic countries. However, 7 autochthonous insect-borne human cases of Chagas disease have occurred in the US, as well as other cases of acute Chagas disease acquired through laboratory accidents.[78,79] Routine screening of the US blood supply began in 2007, and a study conducted by the Red Cross in 2006 to 2007 revealed that 1 in 4655 donations was positive for *T. cruzi* antibodies.[54] Increased immigration from endemic countries, particularly Mexico, has caused Chagas disease to become an important health issue in the US, Canada, and parts of Europe.[2,3,80]

More than 130 species of Triatominae are recognized, and although more than 50 of these species are known to transmit *T. cruzi*, relatively few of them feed on humans. Certain species show a considerable degree of adaptation to human habitation and are important vectors in transmission of Chagas disease, including *Triatoma infestans* (Argentina, Paraguay, southern Peru), *Rhodnius prolixus (*Colombia, El Salvador, Guatemala, Honduras, southern Mexico, Nicaragua, Venezuela), *Triatoma dimidiata* (Belize, Colombia, Costa Rica, Ecuador, El Salvador, Guatemala, Honduras, Mexico, Nicaragua), *Panstrongylus megistus* (Argentina, Brazil, Paraguay, Uruguay), and *Triatoma brasiliensis* (northeastern Brazil).[2,81] The domesticated species are large (2–3 cm or longer), obligate hematophagous insects that hide in crevices in walls, dark corners, windows, and door frames or in the thatch of roofs and take their blood meals at night. They require a blood meal at each stage of development to grow and mature. Infection lasts for the life of the vector, which can be up to 2 years. Species of *Triatoma* vary from one geographic area to another. In the US, several southern states have host vectors and reservoirs for *T. cruzi*, including opossums, armadillos, and canines.[78,79,82]

Pathogenesis and Pathology

During the acute phase, the lesion at the portal of entry shows a local inflammatory response with infiltration of lymphocytes, monocytes, and giant cells. Parasites are distributed widely throughout tissues, but they have a preference for the following: cardiac, skeletal, and smooth muscle cells; neural cells; and cells of the reticuloendothelial system (Fig. 275.5). The heart becomes enlarged, with interstitial inflammation of the endocardium and myocardium, edema, and focal necrosis in the contractile and conducting system. The cellular infiltrates consist of lymphocytes, monocytes, and plasma cells, as well as parasitized muscle cells.[83]

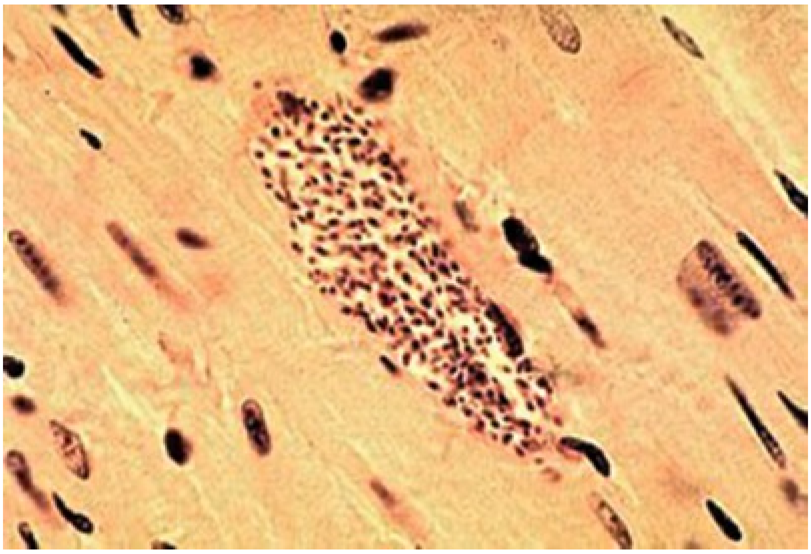

FIGURE 275.5 **Cardiac muscle with a pseudocyst containing amastigotes of *Trypanosoma cruzi*.** (From World Health Organization Tropical Disease Research Library/Stammers.)

During the chronic phase, ganglion cells are progressively destroyed, and the affected organs show variable tolerance to denervation. The heart becomes markedly enlarged, with characteristic thinning of the muscle wall, particularly the right atrium. Mural endocardial thrombosis and aneurysm can occur at the apex of the left ventricle. The myocardium is edematous and congested, myocardial fibers are degenerated, and dense foci of fibrosis can be seen in the interstitial space, but parasites are rarely found (15%–30% of cases). Inflammatory, fibrotic, and vascular changes occur in conductive tissue. The right bundle branch is the most commonly affected, and alterations in the atrioventricular conduction system are frequent. In people with digestive disease, the esophagus and colon are affected most commonly. Fibrosis is present in the myenteric plexus, as well as a considerable reduction in the number of neurons. Dysfunction is related directly to peristaltic abnormalities, which can lead to arrest in transit, extreme dilation of the organ, and hypertrophy of the muscle.[2,83]

Different hypotheses have been proposed to explain the mechanism of organ damage. These include direct cellular destruction by the parasite, cellular damage resulting from exposure to parasite-specific or nonspecific immune responses, microvasculopathy leading to ischemia or inflammation, inflammatory reactions resulting from allergic responses to parasitic antigens absorbed by host cells, or autoimmune reactions to antigens shared by the host and the parasite.[83–85] A clear understanding of the pathogenesis can be complicated by the finding that infections commonly involve a mixture of parasites (polyparasitism), each having distinct pathogenic potential.[86]

The immune system develops specific responses against *T. cruzi* that involve CD4$^+$ and CD8$^+$ T lymphocytes, B lymphocytes, and antibody production. However, complete eradication of the parasite is not achieved, a finding suggesting the development of escape mechanisms by *T. cruzi*. These escape mechanisms involve complement-regulatory molecules on the parasite surface, the ability to escape the phagocytic vacuole, poor pattern recognition receptors, poor development and a narrow recognition scope of *T. cruzi*–specific CD8$^+$ effector cells, and the development of senescence and exhaustion of CD4$^+$ and CD8$^+$ T lymphocytes, respectively.[87–92]

Clinical Manifestations

Clinically, Chagas disease occurs in 3 phases: acute, intermediate, and chronic. The acute phase (4–8 weeks) is often asymptomatic, but it can manifest with prolonged fever, headache, irritability, and fatigue. Infection often goes unrecognized and is diagnosed in only 1% to 2% of all patients. Lymphadenopathy and hepatosplenomegaly are observed frequently, and meningoencephalitis occurs occasionally. Depending on the site of entry, parasites can elicit a local inflammatory reaction of the skin (chagoma) or the eye (Romaña sign) with unilateral periorbital edema, conjunctivitis, and preauricular lymphadenitis (Fig. 275.6).[2,93] The most common (30% of cases) and severe manifestations are cardiovascular disturbances, including cardiac enlargement, functional heart murmurs, conduction blocks, and, occasionally, heart failure. Death caused by acute myocarditis occurs in 2% to 3% of cases, but in patients with meningoencephalitis, the mortality rate can be as high as 50%.[29]

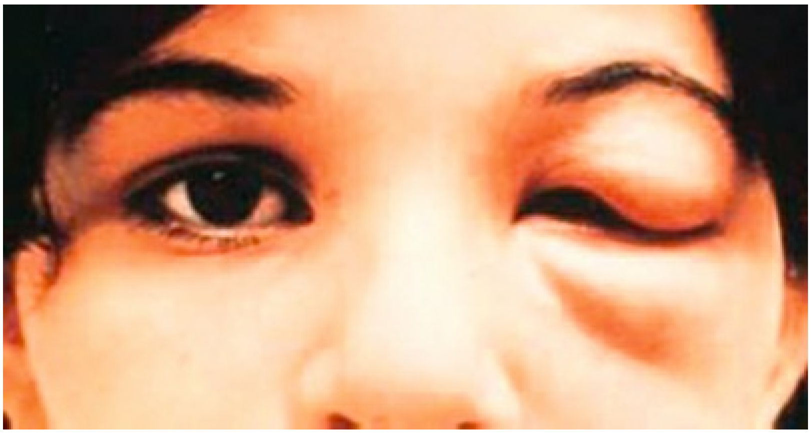

FIGURE 275.6 **Child with acute Chagas disease demonstrating the Romaña sign.** (From World Health Organization Tropical Disease Research Library.)

People who survive enter the indeterminate or chronic asymptomatic phase of the disease. This phase can persist for years, even for the life of the patient, or it can progress 10 to 20 years later to a chronic phase in up to 30% of the people. In the chronic phase, the patient has cardiac, digestive, or neurologic damage. The cardiac manifestations are the most common and include palpitations, dizziness, syncope, dyspnea, and chest pain.[2,3,94] The most important complications are pulmonary embolism and sudden death, usually resulting from ventricular fibrillation. In many cases, a typical aneurysm develops at the apex of the left ventricle.

The digestive form of the disease occurs in 10% to 15% of patients and varies from minor changes in motility of the esophagus or intestine to 2 main syndromes of megaesophagus and megacolon. Patients have difficulty swallowing and regurgitation, severe constipation, and abdominal pain. Esophagitis and esophageal cancer are the most common complications of megaesophagus, whereas fecaloma and volvulus can complicate megacolon.[2,3]

The prognosis depends on clinical staging. The acute phase is most serious in children <2 years of age and is almost always fatal if heart failure or meningoencephalitis develops. In patients with chronic disease and pronounced cardiac manifestations, the prognosis is poor, and death usually occurs within 5 years as a result of heart failure or pulmonary embolism. The prognosis in patients with the digestive form of the disease is usually good.[2,3]

Acute Chagas disease should be considered in any child who has been in an endemic area and in whom myocarditis and an acute febrile illness with lymphadenopathy develop. The acute phase must be differentiated from typhoid fever, visceral leishmaniasis, tuberculosis, toxoplasmosis, malaria, schistosomiasis, cytomegalovirus infection, infectious mononucleosis, and brucellosis. Chronic disease must be distinguished from endomyocardial fibrosis, viral myocarditis, rheumatic heart disease, and carcinoma of the esophagus or colon.

Immunosuppression after organ transplantation or secondary to HIV infection can lead to reactivation of infection and can result in severe systemic disease, which can have manifestations that differ from those in otherwise normal hosts. Transplant recipients often have subcutaneous nodules, panniculitis, and myocarditis, whereas patients with uncontrolled HIV infection can present with meningoencephalitis or focal brain lesions resembling those caused by cerebral toxoplasmosis.[2,93]

Congenital Infection

Congenital transmission of *T. cruzi* can be seen in both endemic and nonendemic countries as a result of immigration and lack of screening. Intrauterine infection can occur at any time during pregnancy and usually is asymptomatic.[64–66,68] Transplacental transmission is the only documented route of transmission, with no significant identification of *T. cruzi* in amniotic fluid or breast milk.[95,96] The risk for vertical transmission is highest in infants born to immunocompromised mothers, with rates as high as 100%.[97] In immunocompetent patients, maternal transmission rates can be as high as 50% in acute Chagas disease, whereas the rate decreases to

2% to 5% in chronic disease. In a study of 530 mothers in Bolivia, 154 (29%) had serologic evidence of chronic *T. cruzi* infection, and the infants of 10 (6%) of these mothers were infected.[68] Studies of infection during 2 periods in Bolivia found a rate of congenital infection of 5%.[64] However, a study in central Brazil showed a transmission rate of 2%, a finding suggesting geographic differences in the rates of transmission that could be directly associated with regional types.[98] In the US, an estimated 130,000 women 15 to 44 years of age were infected in the year 2000, and 170 to 640 cases of congenital infection occurred.[82]

Clinical illness can be present at birth or can develop within the first few weeks of life. The most common findings of congenital infection are prematurity, low birth weight, hepatosplenomegaly, fever, neurologic abnormalities (seizures, hypotonia, hyporeflexia, and tremors), anasarca, and petechiae.[3,64–66,68] Some patients have metastatic hemorrhagic chagomas in the skin or mucosa. Occasionally, intracranial calcifications and ocular lesions can occur. Cardiac involvement is rare and can manifest as heart failure. Megaesophagus and pneumonitis are reported.[3] Laboratory findings can include anemia, thrombocytopenia, lymphocytosis, jaundice, and hyperglobulinemia. CSF studies may reveal pleocytosis with lymphocytic predominance and an elevated protein concentration. Death frequently occurs during the first week of life. Most survivors have severe neurologic sequelae with mental deficiency or behavioral and learning disabilities.[3] Infants of seropositive mothers should be tested as soon as possible for the presence of circulating parasites and specific IgM antibody and should be monitored for a year after birth. A positive serologic test result for specific IgG at 6 and 12 months of age is an indication for treatment. Approximately 30% of congenitally infected patients will develop chronic Chagas disease with the characteristic cardiac and digestive system manifestations.[99]

The differential diagnosis includes TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex) infections, enteroviral myocarditis, disseminated histoplasmosis, and HIV infection. Other diseases, such as erythroblastosis fetalis and hemophagocytic syndrome, should also be considered. In addition to methods used to diagnose postnatally acquired Chagas disease, examination of the umbilical cord can show parasites. Infection of the placenta does not necessarily indicate infection of the baby.

Diagnosis

Microscopic visualization of the organism in blood smears is the optimal method of diagnosis during the acute phase (including early congenital infection), but it is not sensitive in the chronic stage because of low-level parasitemia. Besides examination of stained thick and thin blood smears, examination of fresh blood for motile trypomastigotes can be performed. Concentration methods increase sensitivity. When smears are made, the angle of the "smearing" glass slide should be high, to avoid damaging the trypanosomes, which are delicate. The parasite can be isolated in special culture media.[2,3] Xenodiagnosis entails allowing laboratory-raised triatome bugs, previously fed on birds (which are not susceptible to the infection), to feed on the suspected case, with examination of the feces performed 20 to 25 days afterward. Polymerase chain reaction, where available, may become the optimal method for testing for acute infection, including chronic and congenital infections.[100–102] However, polymerase chain reaction is not currently standardized, and it is not sensitive in the chronic stage of the infection.[2,3] Serologic tests, including enzyme immunoassay, immunofluorescent assay, and indirect hemagglutination methods, are used for screening and diagnosing chronic infection. The diagnosis requires positive results of 2 different tests. If no exposure to vector-borne or blood-transmitted infection occurred, seropositivity after the age of 9 months, by which age maternal antibodies would have disappeared, indicates congenital infection.[2,3]

Treatment

Antitrypanosomal treatment is recommended for all patients with acute and congenital Chagas disease or reactivated infection and for chronic *T. cruzi* infection in children <18 years of age.[103] Drug therapy should be offered to adults 19 to 50 years of age who do not have advanced Chagas heart disease. Drug therapy should not be given during pregnancy, because the drugs are mutagenic, or to patients with severe renal or hepatic disease. Therapeutic options are limited to benznidazole and nifurtimox, neither of which is licensed for use in the US.[104–113]

Treatment is prolonged (60–90 days), with success rates of 60% to 85% in the acute stage of infection, >90% in congenital infection, and 60% (as measured by seroreversion) in early chronic disease in children.[114] Both benznidazole and nifurtimox are well absorbed from the gastrointestinal tract and are active against trypomastigotes and amastigotes. Before initiation of therapy, patients should have complete blood count and serum chemistry studies performed. The blood count should be monitored every 2 to 3 weeks during therapy, and the patient should be examined for dermatologic side effects and peripheral neuropathy. Benznidazole must be compounded in a liquid form for children.[104] Patients with congenital cases have been treated with nifurtimox.[10]

Clinical trials to evaluate alternatives to benznidazole and nifurtimox have not had promising results. The Clinical Trial for the Treatment of Chronic Chagas Disease With Posaconazole and Benznidazole (CHAGASAZOL) compared benznidazole with posaconazole. Although both posaconazole and benznidazole cleared the parasite during the acute phase, significantly more patients who received posaconazole had treatment failure on follow-up.[115] The Proof-of-Concept Study of E1224 to Treat Adult Patients With Chagas Disease tested the efficacy of ravuconazole in comparison with placebo and benznidazole in adults.[11] Although the E1224 trial also showed clearance of the parasite, the rate of treatment failure at 1 year was also higher when compared with the benznidazole arm of the trial. Finally, the Study of the Use of Oral Posaconazole in the Treatment of Asymptomatic Chronic Chagas Disease (STOP CHAGAS), a trial evaluating the combination of benznidazole with posaconazole compared with monotherapy using posaconazole, benznidazole, or placebo, was completed in 2015.[113,116]

Prevention

Improved rates in the diagnosis of disease in acute and asymptomatic stages, screening of blood and of pregnant women from endemic areas, and vector control will help in controlling transmission of disease in humans.

Intestinal Nematodes

Julie R. Harris, Peter J. Hotez

Intestinal nematode infections, sometimes referred to as soil-transmitted nematode, soil-transmitted helminth, or geohelminth infections, are among the most common parasitic infections in humans and affect more than one fourth of the world's population.[1] Studies have affirmed the negative health impact of intestinal nematodes, particularly *Ascaris lumbricoides, Trichuris trichiura*, and the hookworms *Necator americanus* and *Ancylostoma duodenale*, which affect child health and development, including causing physical growth delay, cognitive delay, and malnutrition throughout much of the developing world.[2–4] Studies have questioned the degree of morbidity caused by intestinal nematodes, particularly with low-intensity infections.[5–8] However, multiple studies have demonstrated that chronic intestinal nematode infections during childhood adversely affect school performance and attendance, as well as future economic productivity.[9,10] Information from the Global Burden of Disease Study 2010 indicated that intestinal nematode infections are the leading neglected tropical diseases in terms of disability-adjusted life-years.[11] Infection with these helminths also can have an impact on susceptibility to or clinical progression of other infectious diseases, including human immunodeficiency virus infection, tuberculosis, and malaria.[12–14] In most endemic populations, children are affected disproportionately by intestinal nematodes and often acquire infections of high intensity relative to their adult counterparts living under similar conditions.[1,2] Furthermore, accurate interpretation of clinical studies of nematode infections in children is often complicated by simultaneous infection with several different intestinal parasites.[1,15]

Intestinal nematode infections are encountered occasionally by pediatricians in the developed world.[16] In addition to travelers, children at elevated risk include recent immigrants, refugees, and international adoptees.[17–19] Because *A. lumbricoides, Enterobius vermicularis,* and *Strongyloides stercoralis* are endemic to selected regions of the United States, including the South and Appalachia, infection can also be acquired in the absence of foreign exposure.[20] However, few recent data exist on such infections in the US.[21,22] Intestinal nematode infections are still reported from Eastern Europe.[23,24]

Infection with intestinal nematodes generally occurs by 1 of 2 routes. For *A. lumbricoides, T. trichiura,* and *E. vermicularis,* infection results from ingestion of eggs, sometimes contained in food inadvertently contaminated with human feces. For *Strongyloides (S. stercoralis* and *S. fuelleborni)* and hookworms *(A. duodenale, Ancylostoma ceylanicum, Ancylostoma caninum,* and *N. americanus),* infective third-stage larvae, usually found in soil, penetrate host skin to begin the infective process. Infection with the larvae of *Ancylostoma* and *S. fuelleborni* also can be acquired orally, and these organisms have even been linked to neonatal helminth infections associated with larval ingestion in breast milk. The clinical findings associated with intestinal nematode infections in children are summarized in Box 276.1. Recognized syndromes caused by perinatal infection with *A. lumbricoides, A. duodenale,* and *Strongyloides* are listed in Table 276.1.

Neonatal Syndromes Caused by Intestinal Nematodes

Syndrome	Nematode Species	Speculated Routes of Transmission
Neonatal ascariasis	*Ascaris lumbricoides*	Transplacental
Infantile ancylostomiasis	*Ancylostoma duodenale*	Transmammary, perinatal
Infantile strongyloidiasis (swollen belly syndrome)	*Strongyloides fuelleborni* and *Strongyloides stercoralis*	Transmammary, perinatal

The diagnosis of *Ascaris*, hookworm, and *Trichuris* infection is established most frequently by identification of characteristic eggs in feces (Fig. 276.1). Pinworm eggs are found deposited on the perianal skin. In contrast, *Strongyloides* first-stage larvae, not eggs, are excreted routinely in feces. Serologic testing also can be useful in the diagnosis of strongyloidiasis, especially in lightly infected or asymptomatic people.[25]

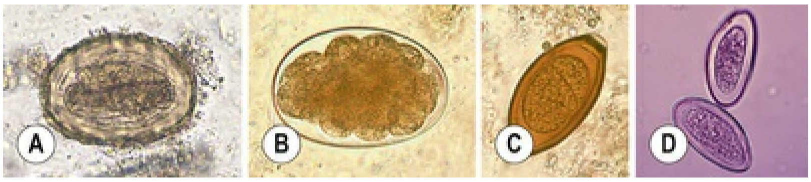

FIGURE 276.1 **Photomicrographs showing the morphologic features of intestinal nematode eggs. (A) *Ascaris lumbricoides*, (B) hookworm, and (C) *Trichuris trichiura* infections routinely are diagnosed by fecal egg examination using light microscopy. (D) *Enterobius vermicularis* eggs are deposited on the perianal skin, and can be removed with adhesive tape and viewed under light microscopy.** (From Centers for Disease Control and Prevention. Benzimidazole anthelmintics remain the cornerstone of therapy for most intestinal nematode infections, including infections caused by *Ascaris*, hookworm, *Trichuris,* and pinworm.[26] Nitazoxanide is also sometimes effective, but it is considered a second-line drug.[27–29] Reductions in morbidity can be achieved even in the absence of complete removal of parasites from the gastrointestinal tract. This observation has catalyzed global efforts to reduce the morbidity from intestinal helminths through widespread use of these agents, efforts that included a resolution passed at the 2001 World Health Assembly to deworm 75% of all at-risk children by the year 2010.[30,31] More recently, the World Health Organization estimated that only one third of the world's 876 million children at risk for intestinal helminth infections receive deworming medication on a regular basis.[32] Moreover, reinfection is common in children in endemic areas, thus necessitating repeated courses of therapy.[33] In addition, high treatment failure rates with mebendazole for human hookworm infection, decreasing efficacy with frequent and periodic use, and the possible emergence of drug resistance in human nematode infections raise important concerns about the widespread use of these agents.[31,34,35] However, in the absence of effective human vaccines or improved global sanitation, targeted chemotherapeutic interventions represent the best current options for control of the major health-related morbidity and mortality associated with intestinal nematode infections.[2]

Ascaris lumbricoides

Epidemiology

Ascariasis is the most common helminthic infection in humans, with an estimated 819 million people infected worldwide.[3,36] As many as 400 million children are infected, and an estimated 51 million children have severe morbidity resulting from heavy infections. Ideally suited to warmer climates, *A. lumbricoides* eggs are resistant to a wide array of environmental stresses. For that reason, ascariasis frequently has both urban and rural distributions and commonly affects children living in economically disadvantaged communities.[37] Ascariasis still occurs in the US as an imported infection, usually in recent immigrants from Latin America and Asia and in internationally adopted children.[18,19,38] Ascariasis likely remains an autochthonous infection in the southeastern US, where the rate of infection in children has historically ranged from 0.8% to 67%; however, more recent estimates are lacking.[16,17,39]

Chronic ascariasis in childhood can be associated with impaired physical growth and intellectual development, which in some cases can be linked to vitamin A and other micronutrient malabsorption as well as protein-calorie malnutrition.[40–43] Young children also are more susceptible to life-threatening complications such as intestinal obstruction, perforation, and peritonitis. Globally, intestinal and biliary tract obstruction caused by *Ascaris* accounts for 10,000 to 100,000 deaths a year, mostly in children.[44,45] In the developing world, the rate of complications secondary to ascariasis ranges from 11% to 67%, with intestinal or biliary tract obstruction the most common serious sequela.[45] Transplacentally acquired neonatal ascariasis also has been described, and its global incidence may be underestimated.[46,47]

The life cycle of *A. lumbricoides* in humans begins with ingestion of embryonated eggs that have been deposited in moist soil. Bile salts and the alkaline pH of the small intestine cause the eggs to hatch. Emerging second-stage larvae penetrate the bowel wall and ultimately invade the microcirculation of the lamina propria. Once in the circulatory system, larvae are carried to the liver through the portal veins and eventually are swept into the pulmonary vasculature, where they lodge in capillaries and rupture into the alveolar space. After ascending the bronchi to the trachea, larvae are swallowed and again migrate to the small intestine. *Ascaris* larvae mature into sexually differentiated adults in the lumen of the small bowel, mate, and begin laying eggs. If egg laying precedes mating, infertile eggs are produced.

Clinical Manifestations

Illness associated with ascariasis can be attributed to the migration of both larvae and adult worms. As larvae migrate through the lung parenchyma, they cause both mechanical and immune-mediated damage. Pulmonary microhemorrhages from ruptured alveolar capillaries result in inflammation and exudation of fluid. Neutrophils and eosinophils are recruited to the lung, perhaps in response to secretory products released by the migrating larvae. Pulmonary infiltrates in association with cough, dyspnea, wheezing, and mild hemoptysis (Löeffler pneumonia) can occur and last up to 2 weeks. In some regions of the world, this so-called verminous pneumonia, which can resemble asthma, is seasonal, occurring among cohorts of children following spring rains.[48] The intensity of illness caused by migrating larvae is proportional to larval numbers, with lightly infected people often having few if any pulmonary symptoms. In rare instances, migrating adult worms can obstruct the airway and cause respiratory distress.[49]

Symptoms associated with the presence of adult *Ascaris* worms in the small bowel include epigastric pain and diffuse abdominal discomfort. Because adult worms can grow to 40 cm in length, heavy infestations can result in acute intestinal obstruction and perforation, especially in the region of the ileum, that require emergency medical or surgical intervention (Fig. 276.2). Migration of adult worms into the biliary tree and then to the liver or pancreas, sometimes elicited by ingestion of certain irritants, can precipitate acute cholecystitis, hepatitis, or pancreatitis. Hepatic abscess can occur if the intrahepatic ducts are obstructed.[45,50]

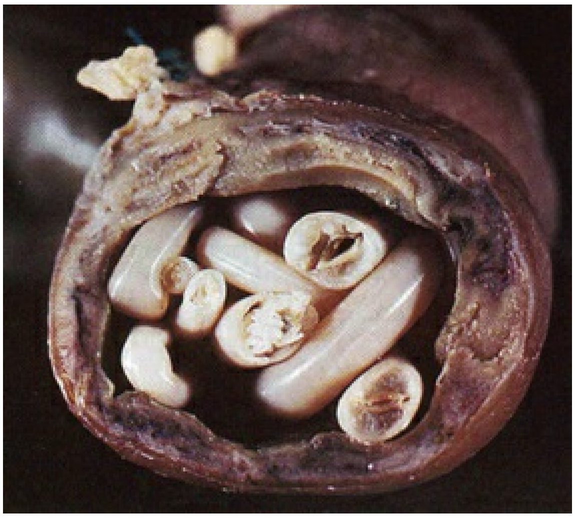

FIGURE 276.2 Surgical specimen showing adult *Ascaris lumbricoides* obstructing the small intestine. (From Meyers WM, Neafie RC, Marty AM, et al. Pathology of Infectious Diseases, vol 1: Helminthiases. Washington, DC, American Registry of Pathology, 2000.)

Chronic ascariasis has been associated with malnutrition, which is caused by malabsorption of dietary protein, fat, and vitamin A. The pathogenesis of malabsorption probably is multifactorial.[40,51] Investigators have postulated that adult worms successfully compete for nutrients by secreting a variety of enzymes and protease inhibitors into the environment of the proximal part of the small intestine. Whether the physical and mental growth retardation syndromes associated with chronic ascariasis in childhood have a purely nutritional basis remains unknown. Furthermore, *Ascaris* infection frequently occurs in the setting of infection with other intestinal nematodes, especially *Trichuris* and hookworm, thus making it difficult to ascribe longterm sequelae to an individual parasitic species.

Laboratory Findings and Diagnosis

The diagnosis of *Ascaris* infection is best established by examination of stool for characteristic ova (see Fig. 276.1). Each adult female produces so many eggs that a single stool specimen usually is adequate. The presence of unfertilized eggs (more elongated than fertilized eggs) still mandates treatment because even a single adult worm represents a risk for serious illness associated with migration.

When migration of *Ascaris* larvae through the lungs is associated with peripheral blood eosinophilia and pulmonary infiltrates on a chest radiograph, examination of sputum can reveal eosinophils and Charcot-Leyden crystals. The differential diagnosis includes other causes of verminous pneumonia, including strongyloidiasis, toxocariasis (visceral larva migrans), and hookworm infection.

In areas endemic for *A. lumbricoides,* any child manifesting acute abdominal symptoms consistent with intestinal obstruction or perforation should be evaluated for ascariasis. Occasionally, an adult worm is present in vomitus. Abdominal radiographs after barium administration can reveal the nature of the intestinal obstruction caused by *A. lumbricoides,* whereas computed tomography with oral contrast can demonstrate cylindric filling defects.[52] Endoscopic retrograde cholangiopancreatography and ultrasonography can be helpful in identifying adult *Ascaris* worms in the intestinal tract or hepatobiliary tree.[53–56] Occasionally, however, the diagnosis of intestinal ascariasis is made at laparotomy.

Treatment

Benzimidazoles, such as mebendazole (100 mg twice a day for 3 days or 500 mg once) and albendazole (400 mg in a single dose), are effective for treatment of intestinal ascariasis, with cure rates >90%.[2,57] Because of their teratogenic and tumorigenic potential, benzimidazoles generally are not given to children <2 years of age. However, wide experience with the use of these agents in children suggests that at a reduced dose (200 mg), administration of albendazole to children 12 to 24 months of age or even children <12 months of age is not problematic. For this reason, benzimidazoles increasingly are being distributed in low- and middle-income countries with heavy disease burdens.[58–60] Ivermectin (150–200 μg/kg once) is also highly effective[61]; however, the safety of ivermectin has not been studied children <15 kg, nor is it approved by the US Food and Drug Administration for ascariasis. Nitazoxanide is comparable to albendazole for treatment of *Ascaris* infections and is approved for use in children ≥12 months of age.[27,28,62–64] The recommended dose is 100 mg (5 mL) twice a day for children 12 to 47 months of age, 200 mg (10 mL) twice a day for children 4 to 11 years of age, and 500 mg twice a day for older children and adults, to complete a 3-day course. Pyrantel pamoate (11 mg/kg up to maximum 1 g/day for 3 days) is a suitable alternative.[31] In some heavily infected children, malnutrition, steatorrhea, and growth retardation are partially reversible with treatment.[64]

In cases of partial small bowel obstruction caused by *Ascaris,* some physicians recommend alternative therapy with piperazine citrate, which paralyzes the worms and can abrogate the need for surgical intervention. However, this drug is no longer available in the US. Piperazine and pyrantel pamoate are antagonistic and should not be given concurrently. Mineral oil or Gastrografin (a solution of diatrizoate meglumine and diatrizoate sodium) given orally or by nasogastric tube also can cause relaxation of the obstructing bolus of worms.

Standard supportive measures for treatment of small bowel obstruction also should be administered, including intravenous hydration, nasogastric suctioning, and monitoring of electrolyte status. Laparotomy to remove the adult worm bolus should be undertaken in patients who do not respond to therapy with anthelmintic drugs.

Prevention

Prevention of ascariasis requires elimination of contact with soil contaminated by egg-containing feces. Although *Ascaris* eggs are killed by prolonged exposure to sunlight or temperatures >40°C, they can survive in extremely cold temperatures for many months and are resistant to many chemical disinfectants. *Ascaris* eggs survive in temperate climates and urban environments.

Diagnosis and effective treatment with improved sanitation practices are the most reliable means of preventing the spread of *Ascaris*.[65,66] In endemic areas where the prevalence of infection with soil-transmitted helminths, including *A. lumbricoides*, is >50%, the recommendation is to administer anthelmintic agents to school-aged children twice yearly as part of a targeted deworming program; prevalences of 20% to 49% indicate annual treatment.[67,68] However, the effects of a single intervention are likely to be shortterm given the inevitability of reinfection. Because ascariasis is an infection that is associated with poverty and poor sanitation, improved water, sanitation, and hygiene, together with sustained economic growth, are requirements for longterm parasite control.

Hookworm (*Ancylostoma duodenale, Ancylostoma caninum, Ancylostoma ceylanicum,* and *Necator americanus*)

Epidemiology

Approximately 439 million people harbor hookworms in their gastrointestinal tracts, and hookworm infection remains a leading cause of iron deficiency, iron deficiency anemia, and protein malnutrition in the developing world.[3,36,69] Children and women of reproductive age (especially pregnant women) are particularly vulnerable to the morbid effects of hookworm infection, often because dietary intake fails to compensate for intestinal losses of iron and serum proteins.[70,71] Although once highly endemic in the southeastern US, hookworm infection was essentially eradicated in the US by the 1920s.[72,73] Pockets of autochthonous hookworm infection still may be present in parts of the rural south, although hookworm is no longer a public health problem in the US.[20]

The 2 most common species of hookworm that infect humans are *A. duodenale* and *N. americanus*, with estimates from the 1940s suggesting that *N. americanus* was responsible for more than 80% of human infections worldwide.[74] *N. americanus* is significantly more common in the Western Hemisphere, Southeast Asia, and Africa, although *A. duodenale* infection and mixed infections occur commonly. Other species that cause intestinal disease in humans include *A. ceylanicum* (Southeast Asia and India) and *A. caninum* (the dog hookworm), which has been implicated as a zoonotic cause of eosinophilic enteritis in Australia and the US.[75–77]

The external life cycle of the hookworm begins when eggs are deposited in moist soil. Eggs develop optimally at ambient temperatures of 20° to 30°C in the absence of direct sunlight. These conditions generally are achieved in association with cultivation of certain crops, such as mulberry leaves and sweet potatoes in China, tea in India, and coffee in Latin America. Thus, unlike ascariasis and trichuriasis, which can occur in urban slums, hookworm infection occurs primarily in rural areas.[37] On hatching, the emerging larvae molt twice to nonfeeding, infective third-stage larvae, which can migrate vertically in the soil in response to changing conditions of moisture. Infection occurs by 1 of 2 routes, depending on the species of hookworm. Whereas both *Ancylostoma* and *Necator* can penetrate the skin, *Ancylostoma* larvae also are infective orally, and in some areas the oral route of infection predominates. Once in the host, third-stage larvae resume development while migrating through the lymphatics and venules to the pulmonary circulation. After traversing the alveolar capillaries into the alveoli, larvae ascend the airways, are swallowed, and travel to the small intestine. Epidemiologic evidence indicates that some hookworm larvae of *A. duodenale* undergo developmental arrest within the host, where they await environmental or hormonal cues before resuming migration to the gut. This phenomenon may explain seasonal variations in fecal egg concentrations, as well as possible transmammary hookworm infection in newborn infants.[78,79]

Once in the small bowel, adult hookworms attach by their mouths to the intestinal mucosa and begin to feed (Fig. 276.3). Equipped with teeth, cutting plates, or both, as well as powerful esophageal muscles and hydrolytic enzymes, the hookworm digests the plug of tissue within its buccal capsule.[80,81] At the same time, potent anticoagulants and inhibitors of platelet function are released and cause profound bleeding from lacerated capillaries in the lamina propria (Fig. 276.4).[82–84] The ingested blood is acted on by hemoglobin-digesting proteases lining the parasite gut.[85,86] Adult worms mate in the small intestine, and the females deposit fertilized eggs in the lumen. A period of approximately 5 to 9 weeks is required after infection for eggs to appear in the feces, or longer in the case of developmentally arrested larvae.

Clinical Manifestations

Skin penetration by third-stage larvae can be associated with an intensely pruritic form of dermatitis called ground itch, which usually is localized to the site of hookworm entry.[87] Ground itch is followed within a week by cough, which occurs when hookworm larvae enter the lungs. Hookworm pneumonitis usually is less severe than the verminous pneumonitis resulting from ascariasis, although it can last for several weeks. Wakana disease, a severe, immediate hypersensitivity-like syndrome characterized by nausea, vomiting, dyspnea, and eosinophilia, can occur after oral ingestion of a large number of infective *A. duodenale* larvae.[88]

The presence of adult hookworms in the small intestine can cause nonspecific gastrointestinal tract symptoms including abdominal pain, even before the onset of anemia. Blood loss secondary to hookworm infection generally is proportional to the worm burden and develops approximately 10 to 20 weeks after infection. *A. duodenale* infection usually is associated with greater blood loss than occurs with *N. americanus*.[89] Hookworm disease and anemia result when blood loss exceeds the host's iron reserves and dietary intake. Longstanding moderate or heavy hookworm infection causes serious iron deficiency anemia associated with pallor, chlorosis (a greenish yellow skin discoloration), dyspnea on exertion, and fatigue.

Children in the developing world are particularly vulnerable to the effects of hookworm anemia because of increased iron requirements and underlying nutritional deficiencies.[90] Growth and developmental delay, as well as learning disabilities, are common in chronically infected children.[91] Many of these effects can be attributed to iron deficiency, but hookworm-associated plasma protein loss and malabsorption also contribute to the clinical manifestations.[92,93] At least some of the malabsorption associated with hookworm infection may result from the secretion by the adult parasite of a potent inhibitor of digestive enzymes.[94,95] Hookworm disease also is an important problem among pregnant women in the developing world and can result in severe maternal anemia, low birth weight in infants, and reduced infant survival rates.[69,71,96]

A fulminant form of gastrointestinal tract hemorrhage related to acute hookworm infection has been described in newborn infants. These children, often <2 months of age, have melena, abdominal distention, and hypotension, with hematocrit values as low as 2% to 3%.[79,97] This condition is seen primarily in children infected with hookworms of the genus *Ancylostoma,* and investigators have speculated that larvae can be transmitted through the milk of chronically infected mothers. A similar route of vertical transmission has been shown to occur in infants in Papua New Guinea who are infected with *S. fuelleborni.*

Infection of humans with the dog hookworm *A. caninum* has been implicated as a cause of eosinophilic enteritis, particularly in northeastern Australia.[76,77] This condition, characterized by intense abdominal pain and peripheral blood eosinophilia, can mimic appendicitis or intestinal perforation. Laparotomy often reveals only a single adult canine hookworm attached to the intestinal mucosa. In addition, asymptomatic aphthous ileitis with eosinophilia has been reported in association with zoonotic infection with *A. caninum.*[98]

Laboratory Findings and Diagnosis

Acute infection, characterized by symptoms associated with migration of infective hookworm larvae, is diagnosed on the basis of clinical findings. The characteristic rash of ground itch occurs on any skin surface and can be erythematous, papular, or vesicular.[87] Intense pruritus can lead to scratching, excoriation, and secondary bacterial infection. In contrast to *Ascaris* pneumonia, the pulmonary symptoms of hookworm pneumonia usually are not severe.

Eosinophilia, which generally is mild, coincides with development of adult hookworms in the intestine.[99] Intestinal hookworm infection is detected by identifying the characteristic eggs in feces (see Fig. 276.1). Because most symptomatic people excrete large numbers of eggs, stool-concentrating techniques usually are not necessary to detect clinically relevant infections. Although hookworm secretory antigens can be detected in feces of infected laboratory animals,[100] fecal antigen tests are not available for diagnosing human infections. The eggs of *Ancylostoma* and *N. americanus* are similar under light microscopic examination and cannot be distinguished easily on the basis of morphologic features.

Treatment

Single doses of mebendazole are inadequate for treatment of human hookworm infection; higher cure rates have been reported after multiple doses of mebendazole (100 mg twice a day for 3 days) or albendazole (400 mg once).[31] Although the safety of benzimidazoles in children has not been established definitively, these compounds are the drugs of choice for children with intestinal helminth infections. Nitazoxanide may be effective in treatment of hookworm infections,[101] but comparative data with albendazole are lacking. An alternative treatment is pyrantel pamoate (11 mg/kg/day, not to exceed 1 g/day, for 3 days), which has been reported to be effective in treatment of infantile ancylostomiasis. Unfortunately, reports suggest the possibility of anthelmintic drug resistance among human hookworm isolates, based either on drug failure or diminishing efficacy with increasing drug use.[34,35]

Mebendazole is absorbed poorly and thus may not eradicate developmentally arrested *Ancylostoma* larvae residing in extraintestinal tissues. Therefore periodic follow-up stool examinations can be necessary to detect latent infection. Moreover, reinfection in endemic areas occurs so commonly that the effect of a single course of an anthelmintic drug is of questionable benefit. Iron supplementation reverses mild to moderate hookworm anemia and can lead to improvement in growth and intellectual development.[56] Severe and acute gastrointestinal tract hemorrhage caused by hookworm rarely can lead to hemodynamic compromise necessitating blood transfusion.

Prevention

Use of shoes can be protective under some circumstances for hookworm and other neglected tropical diseases.[66,102] However, compliance is often difficult, and both major hookworm species can penetrate all aspects of the skin, including the legs, buttocks, abdomen, hands, and arms.[103] At least shortterm benefits in iron status have been demonstrated in heavily infected children treated with albendazole or mebendazole.[2,104,105] However, no evidence of naturally acquired resistance to hookworm infection has been reported, and children in endemic areas are constantly exposed to infective third-stage larvae. In addition, arrested larvae within the host can be resistant to currently available anthelmintic agents. For these 2 reasons, mass or targeted chemotherapy programs alone may not control hookworm infection in many parts of the developing world. As a result, renewed interest has been shown in the development of vaccines.[106] To date, the most promising vaccine candidates are recombinant forms of 2 enzymes involved in parasite blood feeding, with a series of clinical trials planned in coming years.[107–111]

Trichuris trichiura

Epidemiology

Approximately 465 million people worldwide are infected with the whipworm *T. trichiura,*[36] which is distributed throughout the tropics and subtropics.[1,112] Named for its characteristic shape (Fig. 276.5), the adult stage of *T. trichiura* is an important cause of inflammatory bowel disease in children from the developing world. Children with trichuriasis usually have greater numbers of whipworms than their adult counterparts and suffer disproportionately from clinical trichuriasis.

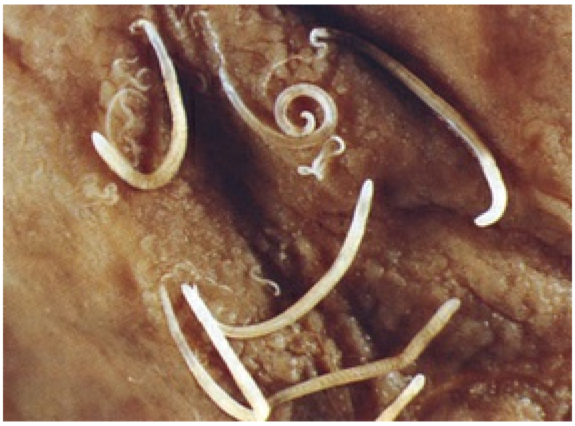

FIGURE 276.5 **Photograph of adult *Trichuris trichiura* attached to the colonic mucosa.** (From Meyers WM, Neafie RC, Marty AM, et al. Pathology of Infectious Diseases, vol 1: Helminthiases. Washington, DC, American Registry of Pathology, 2000.)

Fertilized *Trichuris* eggs require 3 to 4 weeks in a warm, moist environment to embryonate and become infectious. After ingestion, second-stage larvae hatch and penetrate mucosal epithelial cells of the cecum or colon. The worm expands intracellularly and ultimately creates tunnels within the epithelium to accommodate growth (Fig. 276.6). The thickened posterior portion of the worm eventually ruptures the cell membrane and protrudes into the lumen of the large intestine. In this manner, *Trichuris* can disrupt the normal colonic architecture. However, a large component of the pathogenesis of trichuriasis results from the host inflammatory response mediated by cytokines produced by T lymphocytes and macrophages.[113,114]

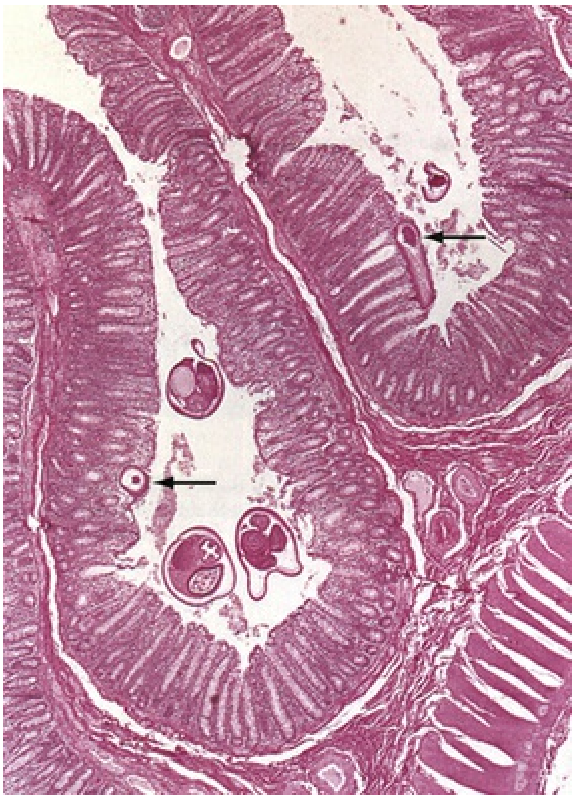

FIGURE 276.6 **Photomicrograph of an intestinal biopsy specimen showing sections of *Trichuris trichiura* in the colon. Note the anterior portions of adult worm within the colonic mucosa (*arrows*) and the thicker posterior portion in the lumen.** (From Meyers WM, Neafie RC, Marty AM, et al. Pathology of Infectious Diseases, vol 1: Helminthiases. Washington, DC, American Registry of Pathology, 2000.)

Adult whipworms mate, and females lay eggs in the colon, with approximately 5000 eggs deposited per day. A period of approximately 90 days is required to complete the life cycle of the parasite in humans from ingestion of eggs to development of mature egg-laying adult worms.

Clinical Manifestations

Although most whipworm infections are asymptomatic, 2 well-defined clinical entities are associated with heavy infection. The first, *Trichuris* dysentery, is an acute diarrheal disease associated with the passage of blood and mucus in stool.[112] Bleeding is probably secondary to the mucosal damage and inflammation caused by the attachment of adult worms to the colonic epithelium. No evidence shows that *T. trichiura* feeds on blood. The profound mucosal edema associated with *Trichuris* dysentery leads to tenesmus and, in protracted cases, can cause rectal prolapse or even colonic obstruction.[115]

Whipworm infection also can result in chronic colitis that shares many clinical features with other inflammatory bowel diseases such as Crohn disease and ulcerative colitis. In particular, the factors that mediate delay of growth appear to be similar to those found in children with other causes of inflammatory bowel disease.[116] In patients with heavy infections, worms also can spread proximally and cause ileitis. In some cases, trichuriasis works in synergy with infection caused by *Campylobacter jejuni* to produce more severe disease.[117]

Diagnosis

Unlike *Ascaris* and hookworms, *Trichuris* commonly is associated with diarrhea. *Trichuris* dysentery can resemble dysentery caused by other pathogens, including enteric bacteria and *Entamoeba histolytica.* Examination of stool for characteristic *T. trichiura* eggs is the most reliable means of diagnosis (see Fig. 276.1). Stool concentration techniques usually are not necessary to detect most symptomatic cases. If stool examination reveals the presence of Charcot-Leyden crystals, *Trichuris* infection is likely.

Important histologic findings distinguish *Trichuris* colitis from other types of inflammatory bowel disease. First, the pathologic changes in the colon resulting from whipworm infection are confined primarily to mucosal epithelium, with little involvement of the submucosa and muscularis layers. In addition, the dramatic symptoms of *Trichuris* colitis are characteristically out of proportion to the modest inflammatory response seen histologically.

Blood tests rarely are helpful in making the diagnosis of trichuriasis. Iron deficiency is a common finding and can be acute (caused by gastrointestinal hemorrhage) or chronic, as occurs in longstanding cases of colitis. The erythrocyte sedimentation rate, which often is elevated in inflammatory bowel diseases, is usually normal in children with whipworm infection.[112]

Treatment

Trichuriasis is considered less responsive to anthelmintic therapy than are other intestinal nematode infections.[31] Longer courses of albendazole (400 mg for 3–7 days) and mebendazole (100 mg 2 times a day for 3–7 days) are recommended for treatment.[57,118] Data are mixed on the efficacy of nitazoxanide against *Trichuris* infections; multiple-day doses can also be required for effectiveness of this drug.[28,101,119,120]An alternative regimen for the treatment of trichuriasis is a combination of albendazole (400 mg) and ivermectin (200 µg/kg), both given in a single dose orally.[60,121] A study of 155 children in Sri Lanka showed a cure rate of 79% after combination therapy, thus making the combination almost twice as effective as with albendazole alone.[122] Although the benzimidazoles generally are considered safe in children, one study in asymptomatic children with trichuriasis demonstrated that these drugs may be associated with growth delay.[123] Other studies, however, have not supported this observation. Oxantel is an alternative drug for trichuriasis and frequently is formulated in a liquid suspension with pyrantel pamoate, which is suitable for young children. This preparation is generally not available in the US. One study has shown a combination of oxantel pamoate and albendazole to be superior to albendazole plus ivermectin, albendazole plus mebendazole, or mebendazole alone against *Trichuris trichiura.*[124] Retreatment of *Trichuris* infections can be necessary, especially for children who remain in endemic areas. Iron supplementation may help resolve the anemia of trichuriasis, as well as speed the rate of catch-up growth. Although treatment speeds physical catch-up growth dramatically, recovery of cognitive skills can be much less pronounced in heavily infected children.[125]

Prevention

Improved water, sanitation, and hygiene measures necessary to reduce the spread of other geohelminthic infections also have an impact on trichuriasis. However, the benzimidazoles used in chemotherapy control programs may have less activity (especially in a single dose) against *Trichuris* than against other intestinal nematodes, thereby necessitating the addition of ivermectin. In addition, raw fruits and vegetables grown in endemic areas where irrigation water is contaminated can harbor and transmit infective eggs.

Enterobius vermicularis

Epidemiology

Along with toxocariasis, infection with the human pinworm *E. vermicularis* may be the most common helminthiasis in the US and other developed countries.[20] Most infections occur in children, with high rates of transmission documented in group childcare facilities, nursery schools, and elementary schools.[17,126] Although enterobiasis is seldom if ever a cause of serious morbidity in children, it often is distressing for parents and guardians. Reassurance by healthcare personnel is an important component in management of pinworm infection.

Infection with *E. vermicularis* occurs after ingestion of embryonated eggs that have been deposited by the adult female worm. Eggs frequently are identified on the perianal skin, thus implicating fecal-oral contamination as the most common route of infection in young children. However, infection by airborne eggs or contaminated fomites also has been described, as well as retroinfection, in which eggs deposited on the perianal skin hatch and give rise to motile larvae that migrate back into the rectum and develop into adults.

After ingestion, pinworm eggs hatch intraluminally, and the emerging larvae descend the small intestine and develop into mature adults on reaching the cecum. Adult female worms live primarily in the colon and migrate out onto the perianal skin, where they lay eggs. Worm migration frequently occurs at night. A female adult pinworm releases up to 10,000 fertilized eggs every 24 hours that embryonate and become infective within 6 hours. Although most eggs remain at the site of deposition, some can be dispersed into the air and contaminate environmental surfaces, or scratching can lead to transmission from contaminated fingers. Eggs can survive several days under conditions of high temperature and humidity. The complete life cycle of *E. vermicularis* can be completed in 4 to 6 weeks.

Clinical Manifestations

The most common symptom of people infected with pinworms is localized pruritus, probably caused by an allergic response elicited against the migrating adult pinworm as it lays its eggs on the perianal skin. Intense itching can result in scratching and excoriation of the area, occasionally leading to secondary bacterial cellulitis. In young girls and women, migrating pinworms can enter the vagina and cause mild vaginitis or even enter the urethra and introduce intestinal bacteria that can lead to lower urinary tract infection. In 1 study, young girls with urinary tract infection were almost twice as likely to have pinworm infection (36% vs. 16%) as were girls with no previous history of urinary tract infection.[127] Rarely, other sites of aberrant pinworm migration have been described, including the fallopian tubes, ovaries, and peritoneum.[128–130] Pinworms also have been associated with perianal cellulitis and granuloma or abscess formation.[131,132] Whether pinworm migration into the appendix is a common cause of acute appendicitis is controversial (Fig. 276.7), but the incidence of pinworm-associated disease appears to be low even in highly endemic areas.[126,133,134]

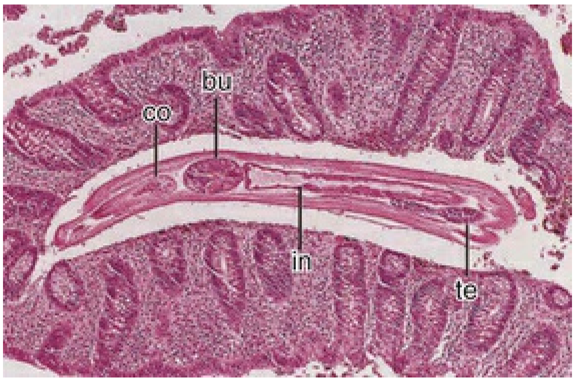

FIGURE 276.7 **Photomicrograph of an intestinal biopsy specimen showing the anterior region of an adult pinworm (*Enterobius vermicularis*) lodged in the lumen of the appendix. Pathology of Infectious Diseases, vol 1: Helminthiases. Washington, DC, American Registry of Pathology, 2000.)

The host-mediated inflammatory response to the intestinal stages of *E. vermicularis* is minimal, although eosinophilic ileocolitis has been reported.[135] However, the lack of prominent gastrointestinal tract complaints in the setting of this infection suggests that significant intestinal disease is rare.

Laboratory Findings and Diagnosis

The most reliable means of diagnosing pinworm infection is examination of transparent adhesive tape that has been applied to the perianal skin. The tape is then removed, placed on a microscope slide, and viewed for the presence of eggs (see Fig. 276.1). This procedure is best performed when the patient arises in the morning or before bathing, and it may have to be repeated on subsequent days to detect infection. *E. vermicularis* eggs are not excreted in the stool, so examination of feces is not helpful.

Serologic tests are not available to detect pinworm infection. Eosinophilia, which has been reported occasionally, is an unusual finding and therefore is not useful in the diagnosis. Adult pinworms, which are sometimes found in tissue specimens, are identified readily by the presence of bilateral cuticular ridges known as alae, which distinguish *E. vermicularis* from other intestinal nematodes of humans.

Treatment

Single-dose therapy with either mebendazole (100 mg), pyrantel pamoate (11 mg/kg, not to exceed 1 g), or albendazole (400 mg) is adequate treatment for pinworm infection.[57] Because none of these drugs is completely effective against eggs or developing larvae, a second treatment 2 weeks after the first is recommended. To date, resistance of *Enterobius* to benzimidazoles has not been reported.

Prevention

Because pinworm eggs can survive for days outside the host, all clothes and bed linens should be washed at the time of treatment. All family members should be treated as a group when multiple or repeated symptomatic infections occur. Within 1 institutional setting, a substantial reduction in the prevalence of pinworm was achieved through targeted chemotherapy of infected people and all potential contacts.[136] In this study, treating all infected people and their contacts with 2 doses of mebendazole 14 days apart reduced the prevalence of *E. vermicularis* infection from 24% to 1% over a 3-year period.

Strongyloides stercoralis and *Strongyloides fuelleborni*

Epidemiology

S. stercoralis can be found throughout both tropical and temperate climates, including parts of the US, particularly eastern Tennessee, Kentucky, and West Virginia.[20,137–140] The prevalence of strongyloidiasis probably is underestimated because of the relative difficulty in detecting subclinical infection. However, groups known to be at particularly high risk of harboring *Strongyloides* include veterans of World War II and Vietnam, refugees from Southeast Asia, and other immigrants to the US.[19,137,141] Epidemiologic studies have demonstrated an increased prevalence of strongyloidiasis in people who also are seropositive for human T- lymphotropic virus type I (HTLV-1).[142–144] Dogs and other mammals also can harbor *S. stercoralis* and can serve as reservoir hosts inasmuch as zoonotic infections in animal handlers have occurred.[145] A distinct and fulminant form of neonatal strongyloidiasis caused by *S. fuelleborni,* called swollen belly syndrome, has been described in neonates from Papua New Guinea.[146]

The life cycle of *Strongyloides* is complex and consists of both a parasitic (homogonic) cycle and a free-living (heterogonic) cycle. Human parasitism occurs initially when soil-borne third-stage filariform larvae penetrate the skin. Some, if not most, of the infective larvae migrate through the lymphatics and venules to the pulmonary circulation, penetrate the alveolar space, and migrate up the pulmonary tree, where they are swallowed and make their way to the small intestine. All parasitic adults found in the small bowel probably are female, and therefore reproduction within the host is likely to occur by parthenogenesis. Eggs deposited into the intestinal lumen release first-stage rhabditiform larvae that are passed in the feces (Fig. 276.8).

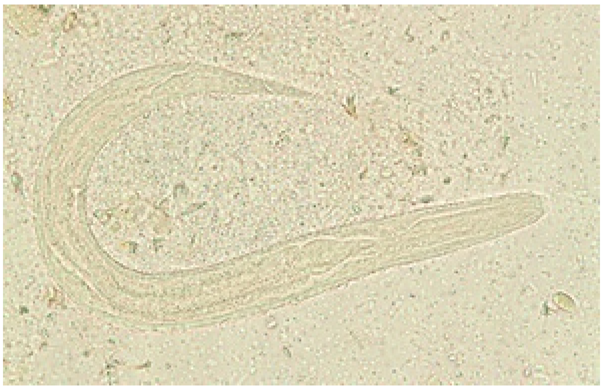

FIGURE 276.8 **Photomicrograph of a *Strongyloides stercoralis* first-stage (rhabditiform) larva excreted in feces. Unlike in most intestinal nematodes, *S. stercoralis* eggs typically are not detected in fecal samples.** (From Centers for Disease Control and Prevention. DPDx. http://dpd.cdc.gov/dpdx/HTML/Image_Library.htm.)

Under certain conditions, larvae do not exit the host in feces but instead molt intraluminally to the filariform stage during transit in the gut. These third-stage larvae can penetrate the intestinal mucosa or possibly the perianal skin and begin the infective cycle anew. This phenomenon, called internal autoinfection, allows *Strongyloides* to be maintained within the host for years after the initial infection. An important point is that the autoinfective cycle can be accelerated in an immunocompromised host and result in an often fatal condition known as hyperinfection.[144]

When first-stage larvae are deposited with feces, they develop in the soil into male or female adults, which mate and lay eggs. Eggs hatch, and larvae either can continue this free-living cycle for 1 or more generations or develop into parasitic filariform larvae and infect a suitable host.

Clinical Manifestations

Acute infection with *Strongyloides* larvae can elicit a cutaneous eruption at the site of skin penetration. This serpiginous urticarial rash, known as larva currens, is thought to represent an allergic response to migrating filariform larvae.[147–149] In chronic infections, such an eruption can be caused when autoinfective larvae penetrate the perianal skin or buttocks.

In immunocompetent patients, strongyloidiasis is an important cause of irritable bowel–like syndrome with intermittent abdominal cramping and diarrhea alternating with constipation.[150] In children, strongyloidiasis is associated with chronic diarrhea, fever, cachexia, and failure to thrive.[138,151] Malabsorption of both fat and protein can lead to a celiac-like syndrome characterized by steatorrhea, hypoalbuminemia, and peripheral edema. Deficiencies of vitamin B_{12} and folate also are common in patients with heavy infections.

A syndrome of infantile strongyloidiasis caused by *S. fuelleborni* has been described in Papua New Guinea.[146,152] Beginning in the first months of life, infected children often have diarrhea that becomes protracted, failure to thrive, protein malnutrition, and a kwashiorkor-like appearance attributable to hypoalbuminemia. Similar syndromes of infantile strongyloidiasis have been reported from parts of Africa. *Strongyloides* larvae have been detected in the milk of mothers with chronic infection, thus suggesting vertical transmission as a possible mode of neonatal disease.[153] Whether *S. stercoralis* also can be transmitted through human milk is not known, although this species has similarly been isolated from very young children.

The most serious complications of strongyloidiasis, hyperinfection and disseminated disease, occur during amplification of the autoinfective life cycle. Several well-defined risk factors for the development of hyperinfection syndrome have been recognized.[150] Most commonly, severe disease develops in patients who are chronically infected with *S. stercoralis* after the initiation of immunosuppressive agents for a variety of underlying conditions. Severe strongyloidiasis has been reported most commonly in patients being treated for hematologic malignant diseases or after solid-organ transplantation.[154] Most of these patients were receiving corticosteroids as part of their antineoplastic or immunosuppressive regimens; this finding raises the possibility that glucocorticoid therapy, even in the absence of malignant disease, can be the primary risk factor for hyperinfection syndrome.[155,156] *Strongyloides* hyperinfection also can occur in patients with generalized inanition and malnutrition, as well as in patients infected with HTLV-1.[143,144] In children with *Strongyloides* hyperinfection, the massive numbers of larvae migrating through the lungs can cause pulmonary infiltrates, dyspnea, and even respiratory collapse. These larvae often migrate aberrantly to distant organs, including the skin, brain, liver, heart, skeletal muscle, and lymph nodes, where they can elicit a vigorous immune response. Disseminated strongyloidiasis can be complicated by pyogenic abscess or meningitis caused by enteric bacteria transported from the colon by migrating worms.[157,158] Eosinophilia, found routinely in people with chronic strongyloidiasis, usually is absent in hyperinfection and disseminated disease. Untreated, *Strongyloides* hyperinfection has high mortality rate.[159]

Laboratory Findings and Diagnosis

Definitive diagnosis of *Strongyloides* infection relies on identification of first-stage rhabditiform larvae in the feces of an infected person (see Fig. 276.8). However, because female *S. stercoralis* nematodes release as few as 50 eggs a day, multiple stool specimens concentrated with the use of various techniques can be required to detect light or chronic infections. As a result, in most cases of uncomplicated strongyloidiasis a single fecal examination misses up to 70% of cases.[160] Several techniques, including an agar culture method, have been developed to increase the sensitivity of larval detection in the stools.[160–162] Alternatively, the number of larvae recovered from feces can be amplified by allowing them to undergo the heterogonic life cycle in Baermann cultures.[156] In patients with hyperinfective and disseminated strongyloidiasis, larvae can be recovered from extraintestinal sites, including sputum, bronchoalveolar lavage fluid, and, in some cases, cerebrospinal fluid (Fig. 276.9).[157]

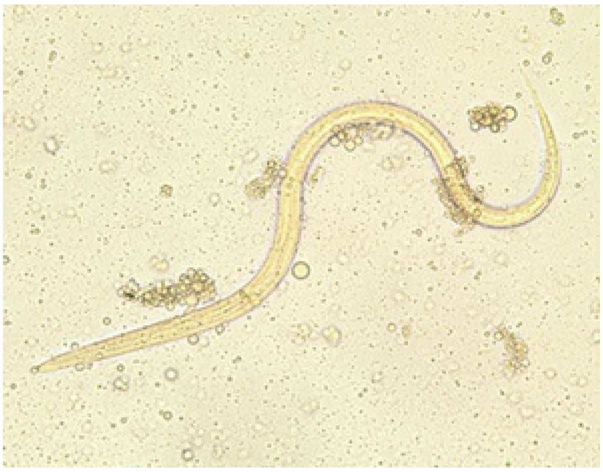

FIGURE 276.9 **Photomicrograph of a *Strongyloides stercoralis* third-stage (filariform) larva.** (From Centers for Disease Control and Prevention. DPDx. http://dpd.cdc.gov/dpdx/HTML/Image_Library.htm.)

Peripheral blood eosinophilia often is the only laboratory abnormality in chronic strongyloidiasis and probably represents an immune response to larvae migrating through host tissues. Eosinophilia frequently is absent in people with hyperinfection. Serologic assays can detect subclinical *S. stercoralis* infection.[163,164] These assays can aid in diagnosis in people from endemic areas who have unexplained eosinophilia.

Treatment

Because of the risk of hyperinfection, all people found to harbor *Strongyloides* should be treated, even in the absence of symptoms. The agent of choice is orally administered ivermectin (200 µg/kg/day for 2 days).[150] Cure rates are up to 97%.[165–169] Ivermectin has not been studied extensively in children and should not be given to children <15 kg. As an alternative, thiabendazole can be administered at a dose of 25 mg/kg twice a day (maximum, 3 g/day) for 3 days. Cure rates >80% have been reported, even in immunocompromised people with intestinal disease.[170] Unlike mebendazole, thiabendazole is well absorbed and has been associated with various side effects, including dizziness, nausea, and anorexia. Albendazole (400 mg, twice a day for up to 14 days) also has been used for treatment of strongyloidiasis,[118] as have combinations of ivermectin together with albendazole.[164]

The mortality rate from disseminated strongyloidiasis approaches 60%, even with aggressive treatment and supportive care. Therapy with ivermectin or ivermectin with albendazole should be continued for at least 7 to 14 days, preferably until the parasite can no longer be identified in clinical specimens.[118] In some cases, prolonged or repeated therapies with ivermectin can be required, and veterinary parenteral or enema formulations have been used in severely ill patients.[171] Concomitant bacterial infections should be treated aggressively with appropriate antibiotics, and exogenous corticosteroid and other immunosuppressive therapy should be tapered quickly. Documenting cure can be difficult because the production of eggs usually is low before treatment. Monitoring the serologic response to treatment, as well as peripheral blood eosinophil counts, can be useful.[172]

Prevention

As with other helminths transmitted in soil, proper sanitation practices as part of a full program of improved water, sanitation, and hygiene can help reduce the spread of *Strongyloides* infection in endemic areas. Attention to the importance of targeting strongyloidiasis, in addition to ascariasis, hookworm infection, and trichuriasis, may alter public health control for this disease through periodic deworming.[173] Prompt diagnosis and treatment of mild or asymptomatic infections should reduce the incidence of disseminated disease. People with unexplained eosinophilia, especially if they have lived in endemic areas, should be evaluated for strongyloidiasis before treatment with immunosuppressive therapy, especially glucocorticoids, is administered.

Key Points

Diagnosis and Management of Intestinal Nematode Infections

Microbiology

- Intestinal nematodes (roundworms) are multicellular parasites with complex life cycles.

- Infection is acquired by ingesting eggs or through skin contact by larvae.

- Adult worms reside in the small intestine (*Ascaris,* hookworm, *Strongyloides)* or large intestine (*Trichuris, Enterobius*).

Epidemiology

- More than 2 billion people living in tropical and subtropical regions are infected with ≥1 intestinal nematode.

- In the developed world, groups at significant risk for infection include immigrants, refugees, and children adopted from endemic regions.

- Most infections acquired in the United States are caused by *Strongyloides stercoralis* or *Ascaris lumbricoides,* which are endemic in the Southeast, or *Enterobius vermicularis* (pinworm), which is widespread and occurs in childcare and preschool settings.

Diagnosis

- Fecal microscopy is the diagnostic test of choice for most intestinal nematodes. In the case of *Strongyloides,* first-stage larvae, not eggs, are excreted in the feces.
- Pinworm *(Enterobius vermicularis)* infection is diagnosed most commonly by visual inspection of the perianal area for evidence of adult worms or by applying adhesive tape to the skin to recover eggs.

Treatment

- Screening and treatment for intestinal nematode infections in immigrants and international adoptees are recommended, even in the absence of symptoms.
- Benzimidazole anthelmintics (albendazole, mebendazole) remain the drugs of choice for treating *Ascaris,* hookworm, *Enterobius,* and *Trichuris* infections; however, anthelmintics are generally poorly effective against *Trichuris*.
- Ivermectin is the most effective treatment for *Strongyloides* infection, but only oral preparations are available routinely.
- Nitazoxanide is a broad-spectrum agent for treatment of parasitic infections and is effective against several intestinal nematodes.

Duration of Therapy

- Most infections are cured with 1 to 3 days of treatment.
- Follow-up stool evaluations are recommended to establish cure or the need for additional treatment.
- Despite therapy, disseminated strongyloidiasis in the compromised host is associated with significant mortality rates.

Tissue Nematodes

Daniel Griffin, Dickson D. Despommier

Parasitic roundworms capable of invasion of human tissues are classified as tissue nematodes. They are found in a variety of ecologic niches that allow for human exposure. Many are present in outdoor environments and are transmitted to children through the ingestion of nonfood substances. The infectious stages of many of these tissue parasites often involve an animal host and can be classified as zoonotic infections. Many of these zoonotic parasitic tissue nematodes can permanently affect the cognitive ability, development, and vision of an infected child. This chapter focuses on some of the most medically relevant tissue nematodes.

Visceral Larva Migrans and Ocular Larva Migrans Caused by *Toxocara Canis*, *Toxocara Cati*, and *Baylisascaris Procyonis*

Besides *Enterobius vermicularis* (pinworm), toxocariasis may be the most common helminth infection in the United States, with seroprevalence in many areas exceeding 10%; however, the true burden of disease resulting from this large number of infections is poorly characterized.[1] Several clinical manifestations can follow exposure to the infectious larval forms of these tissue nematodes. Infected people can develop covert toxocariasis, which is a clinical manifestation of toxocariasis involving wheezing and eosinophilia that can manifest similar to and be misdiagnosed as asthma. Covert toxocariasis is believed to be caused by chronic exposure.[2] Perhaps the most commonly recognized clinical syndrome is visceral larva migrans, which manifests as a febrile illness characterized by multisystem involvement and eosinophilia.[1] Patients can also present with devastating neurologic manifestations (neurologic toxocariasis) or ocular larva migrans, which can be severe with irreversible visual loss resulting from scarring of the retina and in some cases retinal detachment secondary to larval migration to the eye.[3] *Toxocara* spp. infections identified through serologic testing may be associated with longterm cognitive consequences. Measurable reductions in scores on cognitive tests have been demonstrated when comparing children with serologic evidence of *Toxocara* spp. infection with children without such evidence.[4] Longitudinal studies to confirm these findings are still needed, but concern has been raised that the impact of this disease goes far beyond the cases brought to medical attention by symptoms.

Human infection with these tissue nematodes was first described in the 1950s, when a larva was detected in the eye of a child, and a series of children presenting with eosinophilia and severe multisystem disease was reported to be infected with *Toxocara canis* and *Toxocara cati* larva.[5,6] *T. canis* and *T. cati* are common causes of infections of dogs and cats, respectively, whereas *Baylisascaris procyonis,* a third important nematode in this group, commonly infects raccoons.[7] The life cycles and morphologic features of these tissue nematodes share similarities with *Ascaris lumbricoides* in humans, yet the adults of these 3 species have a shorter length than the adult *Ascaris* (Fig. 277.1).

Life Cycle

Human infection with *T. canis*, *T. cati*, or *B. procyonis* is initiated after embryonated eggs are ingested by humans. Humans come into contact with these eggs accidentally when their environment is contaminated by fecal material from dogs, cats, or raccoons that harbor the adult worms (Fig. 277.2).[8,9] After ingestion, the eggs are triggered to hatch, thereby releasing larvae that penetrate the wall of the small intestine and enter the circulation. In humans, the larvae migrate through various tissues, unable to complete their life cycle, and end up dying in the tissues they invade (Fig. 277.3).

When these embryonated eggs are ingested by their definitive host, they undergo the classic ascarid life cycle, including hatching, penetrating the intestinal, and entering the circulation. In the definitive zoonotic host, they migrate to the lungs and are coughed up and swallowed. Then they return to the intestinal tract, where they mature into adult worms after a period of 60 to 90 days from time of egg ingestion.[10] The adult worms produce eggs that are released into the environment and become infective after 2 to 4 weeks of maturation in the soil.[11] Infection can occur through ingestion of eggs, transplacentally, or through breast milk.[12] Although adult worms live for only 4 to 6 months, embryonated eggs can survive for several years in warm, moist soils.

Clinical Features

Toxocariasis is a disease that consistently affects the young, with visceral larva migrans occurring mainly in children <7 years of age and ocular larva migrans in children 8 to 16 years of age.[13] Although these diseases disproportionately affect the young, these helminths also are a recognized and perhaps underdiagnosed cause of disease in travelers.[3] The clustering of infection in children is believed to reflect their frequent exposure to fecally contaminated play environments (e.g., playgrounds, yards, and sandboxes). In addition to young age, risk factors for infection include male sex, pet ownership, low level of education, psychiatric disease, foreign birth, and play in public parks.[1]

With the introduction of larval forms into humans after ingestion of embryonated eggs, a range of pathologic features can occur that largely depends on which tissues are invaded. The clinical presentation appears to vary based on host factors such as the age of the person infected and whether the person is immunologically naïve, as well as pathogen-related aspects such as inoculum size, number of exposures, and tropism of particular strains.[11,14] The pathologic findings are believed to be caused by the host's immune response to dead and dying larvae in the viscera (Fig. 277.4). Patients with visceral larva migrans may present with a febrile illness including eosinophilia, hepatosplenomegaly, bronchospasm, and a myriad of other symptoms depending on localization of the nematode larva. The spectrum of disease that can result includes subclinical infections, less severe covert toxocariasis, and fully symptomatic visceral larva migrans with inflammation and disease in multiple organs. Before liver biopsy was replaced by serologic testing, the liver was a common site for isolating nematode larvae in eosinophilic granulomas.[6] Pulmonary symptoms, potentially confused with asthma, may be accompanied by infiltrates apparent on chest imaging.[2] Myocarditis as well as nephritis can develop. If larvae invade the central nervous system (CNS), then encephalopathy, seizures, and functional intestinal disorders can develop in infected patients.[15–19]

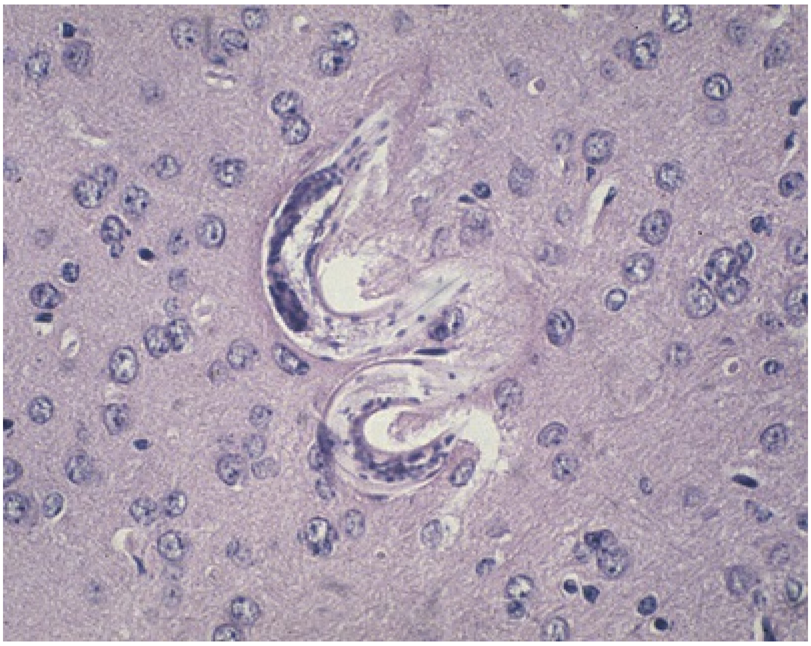

FIGURE 277.4 **The third-stage larva of *Toxocara canis* in the brain of an experimentally infected mouse.**

Ocular larva migrans is a devastating manifestation that tends to occur in people at a slightly older age; it generally manifests in adolescents as visual impairment isolated to a single eye. Larvae that have invaded the retina trigger an immune response as the larvae start to die. This immune response leads to granuloma formation that can result in deformation of the retina and detachment of the macula. In some cases these lesions have been visualized on ophthalmic examination, and because of their visual similarities to retinoblastoma, the risk of unnecessary enucleation of the infected eye exists.[20–23]

Although *Toxocara* spp. infections can be fatal in puppies, death is rare in human infection. When death occurs in humans, it is attributed to involvement of the myocardium or CNS,, along with an overly exuberant immune response when infection is with *T. canis* and *T. cati*. In contrast, infection with *B. procyonis,* a common infection of raccoons, can have high mortality rates.

Humans are exposed to *B. procyonis* through ingestion of embryonated eggs deposited in the environment by raccoons. The increased severity of disease and high mortality rate are attributed to unique features of this tissue nematode. *B. procyonis* larvae are larger, up to 2 mm compared with 0.5 mm for *T. canis* and *T. cati*, and have the unique ability to continue to grow inside the infected human.[24] *B. procyonis* is known as a pathogen to include in the differential diagnosis of eosinophilic meningitis and presents a public health problem because raccoons often enter human environments.[25]

Diagnosis

T. canis, T. cati, and B. *procyonis* infection should be included in the differential diagnosis in a child, adolescent, or returning traveler presenting with an unexplained febrile illness with eosinophilia and a compatible history. A combination of clinical presentation, appropriate risk factors, and a positive serologic test result supports the diagnosis. The recommended test for toxocariasis detects immunoglobulin G against excretory-secretory antigens derived from *Toxocara* spp. larvae. This *Toxocara* enzyme immunosorbent assay is available through the US Centers for Disease Control and Prevention and is estimated to be 78% sensitive and 92% sensitive when the appropriate cutoff is used.[26] One of the challenges of using serologic testing in the diagnosis is that the test detects an immune response to the larval form of the nematode and does not necessarily confirm current active infection. Although a biopsy demonstrating larvae is definitive, this is rarely indicated. The diagnosis of ocular larva migrans also incorporates a consistent ophthalmologic examination (Fig. 277.5). Stool examination of infected people is not helpful because these tissue nematodes are unable to complete their life cycle in humans, and thus adult egg-producing worms are never present in the human gastrointestinal tract. Although a serologic test has been developed for *B. procyonis* that has high sensitivity and specificity, many human cases are not diagnosed until autopsy (Fig. 277.6).

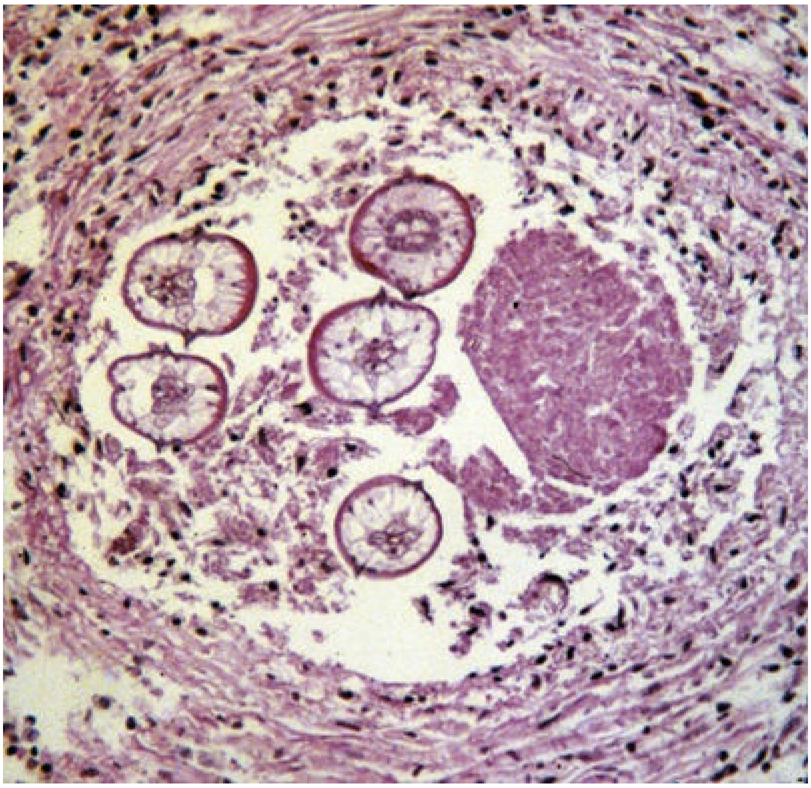

FIGURE 277.6 Larvae of *Baylisascaris procyonis* in brain of a child who died of the infection.

Treatment

Although evidence-based guidance with regard to treatment is limited, patients with *T. canis* and *T. cati* infections can be treated with oral albendazole, 400 mg twice daily for 5 days.[27] In the case of active ocular inflammation, topical and systemic corticosteroids can be used, whereas the role of anthelmintic therapy is unclear because of the lack of knowledge regarding the intraophthalmic pharmacokinetics and pharmacodynamics. The best treatment for *B. procyonis* infection is unclear, but good outcomes have been reported with high-dose albendazole, 25 mg to 50 mg/kg/day in divided doses started promptly and continued for 10 to 20 days, with concomitant corticosteroids.[25,28]

Prevention and Medical Ecology

Limiting human exposure to infective embryonated eggs in the environment is a critical aspect of decreasing the disease burden of these tissue nematodes. Once introduced into the environment, the infective ascarid eggs can remain viable for months to years because of their resistant acellular outer shell that allows them to withstand extreme temperature changes, various degrees of desiccation, and even harsh chemicals.[29,30] Any strategies to rid contaminated soil of these hardy eggs must overcome this barrier.

Once introduced into the soil by the indiscriminate deposition of fecal material by dogs, cats, or raccoons, eggs can be distributed through the environment. The common earthworm is efficient at redistributing fecal material back up to the surface even with eggs initially buried up to 2 feet below the surface.[29] Various domestic animals distribute contaminated soil on their paws, whereas ground-feeding birds such as pigeons, starlings, and sparrows can carry eggs farther afield on their feet and beaks.[10,31]

Eggs also can enter municipal drinking water supplies and end up in waters used for recreational purposes, where inadvertent water ingestion can infect a swimmer.[10] When infected animals deposit these eggs in an environment that allows for their maturation into an embryonated and infective state, the opportunity for continued transmission exists. In this particular public health challenge, veterinarians can have the most striking impact by encouraging pet owners to maintain dewormed pets.

Visceral Larva Migrans Caused by *Angiostrongylus* Spp.

The 2 major *Angiostrongylus* spp. of medical importance are *Angiostrongylus cantonensis* and *A. costaricensis*. *A. cantonensis* is the major cause of visceral larva migrans throughout China, Southeast Asia, and many areas of the Pacific and South Pacific, including Hawaii. *A. costaricensis* is found in Central and South America.

Life Cycle.

Rats are the definitive hosts for *Angiostrongylus* spp. The worms infect several rat species and live and lay eggs in the pulmonary arteries of rats. The released eggs move through the capillaries in the lung and then penetrate the alveolar spaces. From the alveolar spaces, the larvae migrate up the respiratory tree and are swallowed down into gastrointestinal tract ultimately to pass out of the rat in feces.[32] *A. cantonensis* larvae incubate in the soil before being consumed by a variety of mollusks and crustaceans.[33–36] Humans are infected when they inadvertently consume the larval stages of *A. cantonensis* present in uncooked snails, slugs, or raw vegetables contaminated with secretions of these invertebrates.

A. costaricensis larvae generally are restricted to infecting only 1 invertebrate host, the slug, and in most cases the specific slug known as *Vaginulus plebeius* Human infection results when humans accidently ingest these slugs or food contaminated with its secretions.

Clinical Features.

In most cases, human infection with *Angiostrongylus* spp. results in failure of the worm to complete its life cycle. Once in a human host the larvae often migrate to the brain or, rarely, to the lungs as has been observed in infants and small children. Then, the larvae die surrounded by an eosinophil-rich inflammatory infiltrate.[37] The pattern of clinical presentation varies with each species of this nematode. *A. cantonensis* third-stage larvae usually migrate to the meningeal capillaries, where the dying larvae trigger eosinophilic inflammation and resulting eosinophilic meningoencephalitis. Part of the disease can involve vascular thrombosis and aneurysms. *A.*

cantonensis is the most common cause of eosinophilic meningitis outside the developed world and should be considered in the differential diagnosis in travelers returning from endemic areas.[37]

Patients infected with *A. costaricensis* present with fever, bitemporal or frontal headache, and meningismus. Vomiting is reported in most cases, as are migrating painful paresthesias.[38] Investigators have suggested that migrating painful paresthesias often persist for weeks to months along with headaches. Although eosinophilic meningitis is characteristic on cerebral spinal fluid examination, focal lesions are usually not present on head computed tomography or magnetic resonance imaging, and this can finding be useful in distinguishing the disease from other disorders such as *Gnathostoma spinigerum* infection and neurocysticercosis.[39] The natural course of the disease without treatment is for resolution of symptoms in 1 to 2 weeks. Unfortunately, in children disease duration may be longer and severity may be worse.

Diagnosis.

The diagnosis of *Angiostrongylus* spp. is usually based on clinical presentation because serologic testing is not widely available. Confirmation of suspected cases has been achieved using posttreatment serologic testing in concert with research laboratories.[38]

Treatment.

With the self-limiting nature of this disease, treatment options often have focused on symptomatic features rather than on anthelmintic medications. Although animal models have supported the use of anthelmintic therapy trials, efficacy in human infection has not been demonstrated, and reports have noted that anthelmintic therapy may lead to disease exacerbation.[40–42] Serial lumbar punctures and analgesics are the usual approaches to therapy.

Visceral Larva Migrans Caused by *Gnathostoma Spinigerum*

G spinigerum is a parasite that infects a variety of mammals including cats, dogs, and mongooses; its intermediate hosts are copepods, snakes, fish, and birds. The disease is endemic in Southeast Asia and is increasingly recognized in Mexico and Central and South America.[43]

Life Cycle.

G. spinigerum adults live coiled in the wall of the small intestine of their definitive hosts. Eggs are passed out into the environment in the feces and hatch in freshwater. Larvae are released and are ingested by copepods of the genus *Cyclops*. Snakes, fish, and birds then ingest these infected crustaceans. In these intermediate hosts, the larvae mature into a stage infective for humans. When humans ingest infected crustaceans, the larvae are able to exit the gastrointestinal tract and then invade various tissues.[44–46]

Clinical Features.

The clinical features of *G. spinigerum* infection, or gnathostomiasis, are caused by the invasion of deep tissue by these larvae. Although these larvae fail to mature in the human host, they are aggressive migrators and cause direct destruction as well as the host inflammatory reaction.[47] Skin manifestations can include cutaneous larva migrans, panniculitis, and subcutaneous swellings. Invasion of the CNS can occur with peripheral eosinophilia, as well as eosinophilic meningitis with radicular pain and paresthesias caused by larval migration. *G. spinigerum* also can invade the eye and result in intraocular disease.[48]

Diagnosis.

Although previously the diagnosis of gnathostomiasis was limited to an appropriate travel history, clinical presentation, and eosinophilia, diagnostic tests have become available. Enzyme-linked immunosorbent assay and Western blot are now aiding diagnosis, but these tests are not available in the US, and definitive diagnosis is often not possible.[49]

Treatment.

Although this disease can be self-limited, therapy includes a 21-day oral course of albendazole at a dose of 400 mg once daily.[50]

Ivermectin has also been shown to be effective in several trials and can serve as an alternate agent. The role of anthelmintic therapy remains unclear for ocular and neurologic disease, in which this therapy can worsen symptoms. In some cases, corticosteroids have been used in the treatment of patients with CNS manifestations. Unfortunately, relapses have been reported with either therapy.[38]

Cutaneous Larva Migrans Caused by *Ancylostoma Braziliense*

Cutaneous larva migrans is a zoonotic hookworm infection with worldwide distribution that is most often caused by larvae of a dog or cat hookworm, such as *Ancylostoma braziliense, Ancylostoma caninum* (Fig. 277.7), or *Uncinaria stenocephala*. *A. braziliense* is the most common causative organism. These larvae are unable to mature, but on occasion *A. caninum* larvae can migrate to the small intestines in humans and cause eosinophilic enteritis or, rarely, subacute neuroretinitis, rather than cutaneous larva migrans. Other less common nematodes also can cause cutaneous larva migrans, including raccoon-transmitted *Strongyloides procyonis,* which results in "duck hunter's itch."

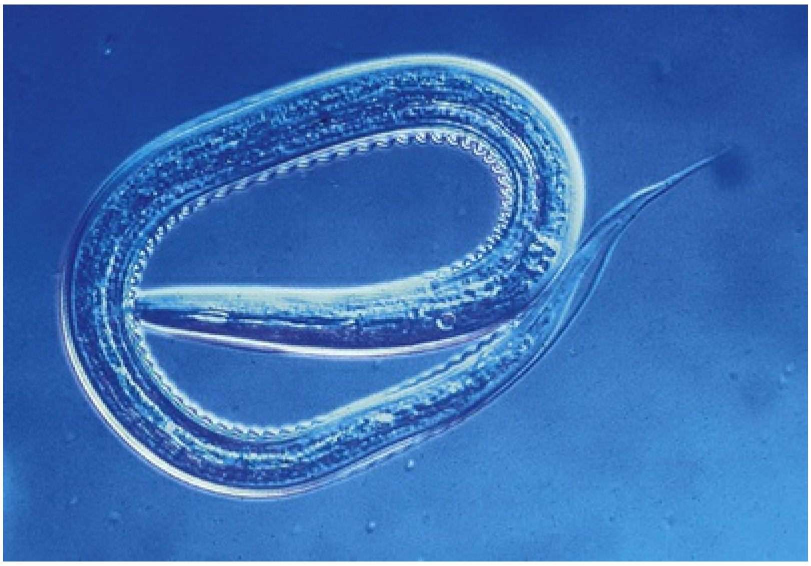

FIGURE 277.7 **Third-stage larva of *Ancylostoma caninum*.** (Courtesy of E. Gravé.)

Life Cycle.

The filariform larvae of these zoonotic hookworms survive in sandy, moist soils for several days. Larvae of zoonotic hookworms are especially common in India and Southeast Asia, Brazil, the Caribbean, and Puerto Rico, where dogs and cats are permitted to defecate.[51] In the human host, infection begins when the filariform larvae penetrate unbroken skin but then fail to receive the proper environmental cues. Instead of going farther in the life cycle, larvae migrate laterally through the deeper layers of the epidermis and can survive there for approximately 10 days.[52] An intense inflammatory reaction, associated with itching in the affected areas, develops within days after larvae enter the dermis and is provoked by hydrolytic enzymes secreted by the larvae.

Clinical Features.

The serpiginous lesions known as “creeping eruption” are evident after an incubation period of 1 week (Fig. 277.8). Secondary bacterial infection caused by scratching is common. In a review of 98 patients with cutaneous larva migrans seen at a travelers' clinic in Munich, 73% of the lesions were found on the lower extremities, with the buttocks and anogenital region (13%) and trunk and upper extremities (7% each) affected less frequently.[53]

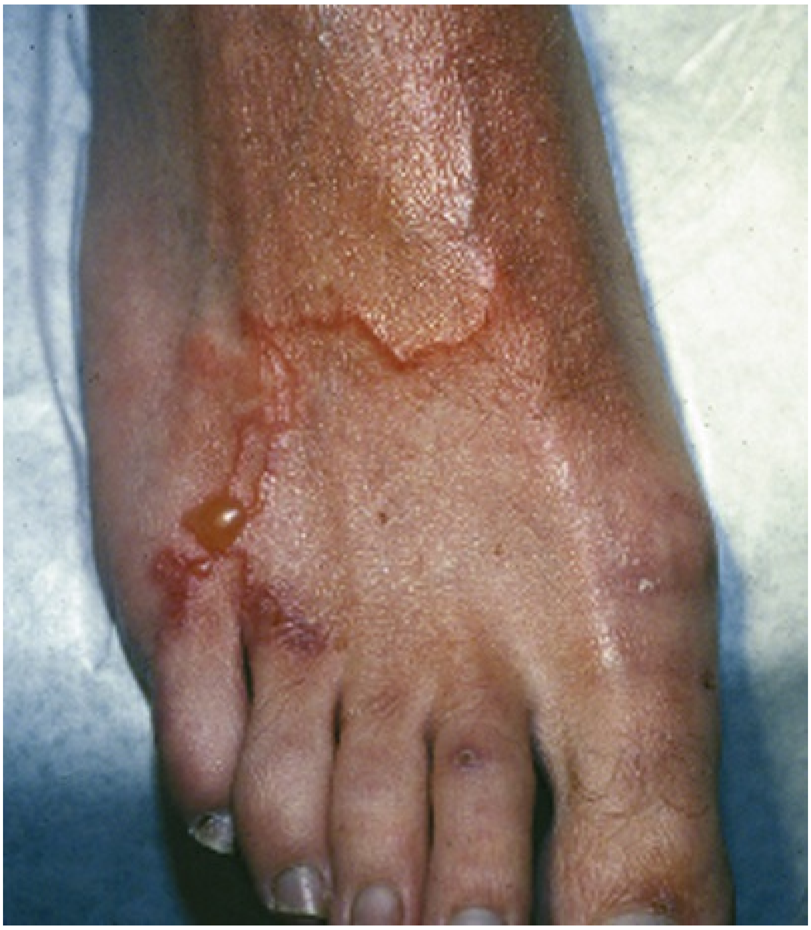

FIGURE 277.8 “Creeping eruption” caused by a larva of *Ancylostoma caninum.* (Courtesy of G. Zalar.)

Diagnosis.

The diagnosis is almost always purely clinical unless one surgically extracts the worm. Some patients have peripheral blood eosinophilia or an elevated serum immunoglobulin E level, but laboratory findings generally play little or no role in establishing a diagnosis.[53]

Treatment.

The treatment of choice is oral therapy with anthelmintic medication. A single dose of ivermectin (200 μg/kg once, sometimes repeated) is considered more effective than a single dose of albendazole, but repeated treatments of albendazole (400 mg daily for 5–7 days) are comparable. Some investigators recommend a 3-day course of albendazole (400 mg daily). Topical thiabendazole in a concentration of 10% to 15% applied 3 times daily for 5 to 7 days is an alternative treatment, but patients' compliance is an issue.

Cryotherapy with liquid nitrogen can cause blistering and ulceration of the skin and should not be performed.[54]

Visceral Larva Migrans Caused by Ascarids of Marine Mammals

Anisakiasis in humans is caused by various species of nematodes belonging to the genera *Anisakis, Phocanema, Terranova,* and *Contracoecum.* The adults of these parasites live in the lumen of the intestinal tract and infect sea mammals, particularly dolphins, whales, sea lions, and seals. Anasakid first-stage larvae infect several crustacean species. Second-, third-, or fourth-stage larvae infect a wide variety of teleosts (bony fish).[55]

Life Cycle.

The adult worms of marine mammal ascarids embed in the gastric mucosa and pass unembryonated eggs out into the environment in the feces. The eggs embryonate, and larvae mature inside the eggs until free-swimming larvae are released. Free-swimming larvae are ingested by crustaceans, and in this host they mature into the stage infective for fish as well as squid. Rather than staying in the intestine of the cold-blooded vertebrate host, larvae migrate to the peritoneal cavity, where they grow up to 3 cm in length. On the death of the vertebrate host, larvae migrate to muscles where they can be ingested by marine predators and develop into adult worms. After embedding into the mucosa, adult female worms begin laying eggs, and the life cycle is complete.[56]

Humans are accidental and dead end hosts for marine ascarids. Humans can become infected when they ingest raw or undercooked marine fish. In humans, the ingested larvae mature and quickly attempt to penetrate the gastric or intestinal mucosa.[57]

Clinical Features.

Infected people often present with abdominal pain that can be severe. The time from ingestion of parasites to the onset of symptoms is usually a matter of minutes to hours. Nausea, vomiting, abdominal distention, mild fever, and diarrhea with blood and mucus in the stool can be part of the presentation.[58] If larvae are able to penetrate the mucosa, then angioedema, urticarial, and allergic symptoms can dominate the clinical presentation.[59]

Diagnosis.

Definitive diagnosis and treatment are accomplished by removal of the parasite. Sometimes the worms are expelled through coughing or vomiting, but at other times endoscopic removal or surgical intervention for extraintestinal manifestations is necessary. Serologic tests using an antigen capture enzyme-linked immunosorbent assay are available in some countries and have a sensitivity reported to be nearly 100%.[60] Polymerase chain reaction (PCR)–based tests have been developed but are not commercially available.[61]

Treatment and Prevention.

Currently, no anthelmintic therapy is approved by the US Food and Drug Administration for the treatment of marine ascarid infection, but successful treatment has been reported with oral albendazole 400 mg twice daily for 6 to 21 days.[62,63] Thorough cooking or freezing of seafood before ingestion can prevent infection by anisakid nematodes. Most sushi restaurants in the US and elsewhere now inspect pieces of raw fish carefully before serving them, and the Food and Drug Administration requires freezing before raw fish are served. Flash freezing in liquid nitrogen has become a popular way of processing fish destined for sushi restaurants. After a peak in the 1980s, the incidence of anisakid visceral larva migrans in Europe and North America from the consumption of raw fish has been reduced to a few sporadic cases annually.[64]

Trichinella Spiralis (Trichinellosis)

The genus *Trichinella* has undergone revision since the advent of reliable DNA probes. Eight species and 11 genotypes are now recognized, all capable of infecting humans.[65–67] Members of the genus *Trichinella* can infect a broad spectrum of mammalian hosts, thus making these organisms the cause of one of the world's most widely distributed nematode infections. *Trichinella* spp. are genetically related to *Trichuris trichiura* and *Capillaria* spp.; all belong to the family Trichurata. These roundworms constitute an unusual group of organisms in the phylum Nematoda in that they all live their lives as intracellular parasites.

Diseases caused by *Trichinella* spp. are referred to collectively as trichinellosis. Currently, the prevalence of trichinellosis is low in the US, with infections occurring mostly as scattered outbreaks, less often involving pork consumption and more often involving poorly cooked game.[68,69] Most human cases are caused by *Trichinella spiralis,* and the information that follows concentrates on this species.

The domestic pig is the main reservoir host for *T. spiralis. T. spiralis* is significantly more prevalent in parts of Europe, Asia, and Southeast Asia than in the US. In Europe, and especially in Eastern Europe, the rise of trichinellosis has been associated with certain political and socioeconomic changes that resulted in a breakdown of the human and veterinary public health infrastructure.[70] Trichinellosis is considered endemic in Japan and China, and a large outbreak occurred in Lebanon in 1997 that infected more than 200 people.[71] In contrast, *Trichinella* spp. infections in wildlife in the US are now thought to be caused largely by the T5 strain, tentatively designated *T. murrelli.*[72]

Life Cycle

Infection is initiated by ingesting raw or undercooked meats harboring the nurse cell–larva complex (Figs. 277.9 and 277.10). Larvae are released from muscle tissue by digestive enzymes in the stomach and then locate to the upper two thirds of the small intestine. The outermost cuticular layer (epicuticle) becomes partially digested, thereby enabling the parasite to receive environmental cues and to select an infection site within the small intestine. Immature parasites penetrate the columnar epithelium at the base of the villus, where they live in a row and are considered intra-multicellular organisms.[73–75]

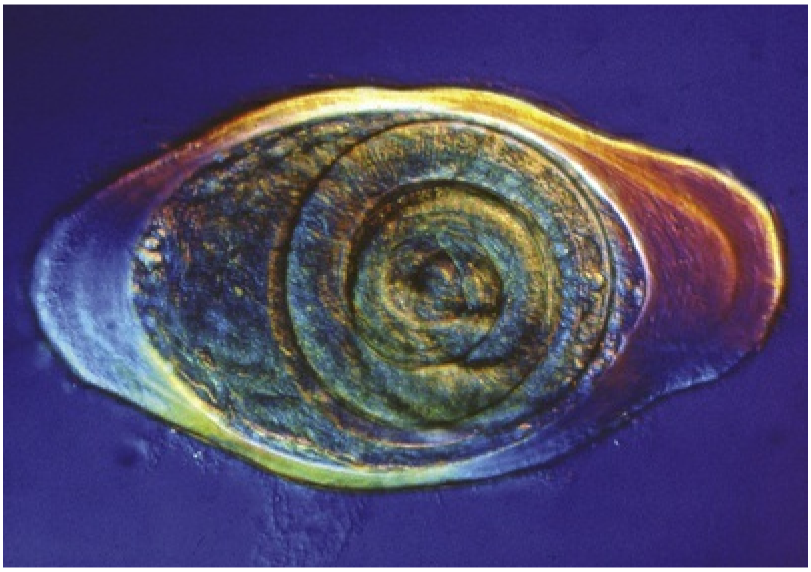

FIGURE 277.10 **Nurse cell–larva complex of *Trichinella spiralis*.**

Larvae molt 4 times in rapid succession over a 30-hour period and develop into adults. The female measures 3 mm in length by 36 µm in diameter, whereas the male measures 1.5 mm in length by 36 µm in diameter. Patency occurs within 5 days after mating. Adult females produce live offspring—newborn larvae, which measure 0.08 mm in length by 7 µm in diameter (Fig. 277.11). The female produces offspring as long as host immunity does not develop. Eventually, the host acquires protective responses that interfere with the overall process of embryogenesis and create physiologic conditions in the local area of infection that force the adult parasites to egress and relocate further down the intestinal tract. Expulsion of worms from the host is the final expression of immunity and can take several weeks.

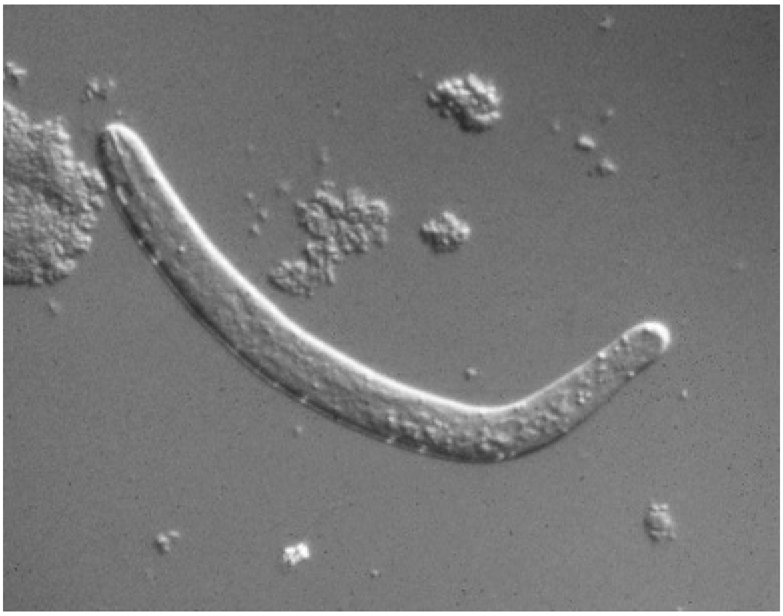

FIGURE 277.11 **Newborn larva of *Trichinella spiralis* (80 × 7 μm).**

The newborn larva is the only stage of the parasite that possesses a sword-like stylet located in the oral cavity that is used to create an entry hole in potential host cells. Larvae enter the lamina propria in this fashion and penetrate the mesenteric lymphatics or the bloodstream. Most larvae enter the general circulation and become distributed throughout the body.

Migrating larvae leave capillaries and enter cells (Fig. 277.12). They appear to have no tropism for any particular cell type, and this cell entry is not limited to muscle cells. Once inside a cell, larvae either can remain or leave, depending on environmental cues received by the parasite. Most cell types die as the result of larval invasion. Skeletal muscle cells are the only exception. Not only do the parasites remain inside muscle cells after invasion, but also they induce a remarkable series of changes, causing the fully differentiated muscle cell to transform into one that supports the growth and development of the larva. This process is termed nurse cell formation.[76] Parasite and host cell develop in a coordinated fashion. *T. spiralis* is infective by day 14 of infection, but the worm continues to grow through day 20. The significance of this precocious behavior has yet to be appreciated.

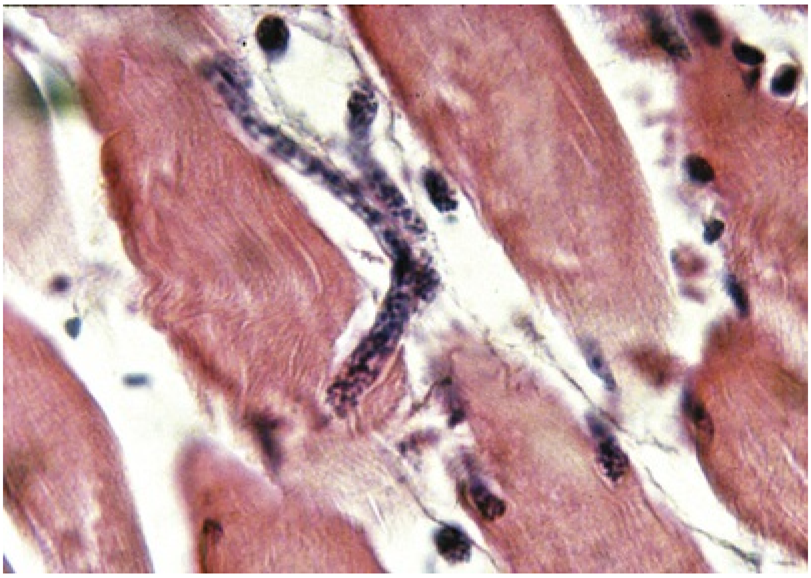

FIGURE 277.12 Migrating larva of *Trichinella spiralis* penetrating outward from a capillary.

Parasites inside cells other than striated muscle cells fail to induce nurse cells and either reenter the general circulation or die. Nurse cell formation results in an intimate and permanent association between the worm and its intracellular niche. At the cellular level, whorls of smooth membranes and clusters of dysfunctional mitochondria replace myofilaments and other related muscle cell components over a 14- to 16-day period. The net result is that the host cell switches from aerobic to anaerobic metabolism. Nuclei enlarge and divide, thus amplifying the host's genome within the nurse cell cytoplasm.[77] The nurse cell–parasite complex can live for as long as the host remains alive. Most do not, however, and are calcified within several months after forming. For the life cycle to continue, an infected host must die and be eaten by another mammal while the parasites are still viable. Scavenging is a common behavior among wild mammals, and this helps to ensure the maintenance of *T. spiralis* and its relatives in their respective host species.

Clinical Manifestations

The presentation of trichinellosis can vary from minimal or subclinical when a limited number of viable larvae are ingested to the distinct 2-stage presentation observed with heavy infection. Some clues, even in the early stages of the disease, can alert the physician to include trichinellosis in the differential diagnosis.

The first few days of heavy infection are known as the gastrointestinal stage. This stage begins 1 to 2 days after ingestion of infected meat and manifests with secretory diarrhea, abdominal pain, and vomiting. These symptoms usually abate within 10 days after ingestion of infected tissue. A history of eating raw or undercooked meats and reporting similar illness in others who ate the same meats are suggestive of trichinellosis.[78]

The parenteral stage begins approximately 1 week after infection and can last several weeks. Typically, the patient has fever and myalgia, bilateral periorbital edema, and petechial hemorrhages, which are seen most clearly in the subungual skin but also are observed in the conjunctivae and on other mucous membranes. Muscle tenderness is detected readily. Laboratory studies reveal a moderately elevated white blood cell count (12,000–15,000 cells/mm^3), with eosinophilia ranging from 5% to 50%.[78]

Larvae penetrating tissues other than muscle give rise to more serious sequelae. In many cases of moderate to severe infection, cardiovascular involvement leads to myocarditis. Electrocardiographic changes are frequently noted during this stage. Parasite invasion of the diaphragm and the accessory muscles of respiration can result in dyspnea. Neurotrichinellosis may occur as a result of CNS invasion.[79,80] A final convalescent stage follows the 2 acute stages of this illness, during which time many nurse cell–parasite complexes are destroyed.

Diagnosis

The diagnosis is established on the basis of appropriate clinical and laboratory findings. These findings include eosinophilia and increases in serum muscle enzyme levels, antibody detection or detection of larvae in muscle, and epidemiologic investigations identifying a source and origin of infection. Muscle enzymes (e.g., creatine kinase and lactic dehydrogenase) are released and cause an increase in serum levels. Results of serologic tests can be positive within 2 weeks; enzyme immunosorbent assay results can be positive as early as 12 days after infection. Definitive diagnosis depends on finding the nurse cell–parasite complex in muscle biopsy by microscopic examination or detecting *Trichinella*-specific DNA by PCR. PCR is sensitive and specific for detecting small numbers of larvae in muscle tissue, but it rarely is used in the clinical setting.[78]

Muscle biopsy results can be negative, even in patients with high-density infections, because of sampling error. In addition, the larvae can be at an early stage of development, thus making them inconspicuous, even to the experienced pathologist. A rising, plateauing, and falling level of circulating eosinophils throughout the infection period is not confirmatory, but in the appropriate clinical context it could warrant empiric therapy. Bilateral periorbital edema, petechiae under the fingernails, and high fever, coupled with a history of eating raw or undercooked meats, further solidifies the diagnosis of a presumptive infection.

Treatment

An anthelmintic should be administered, with the recommended dose of albendazole (400 mg twice daily for 8–14 days). Albendazole results in higher tissue levels and therefore is preferred to mebendazole. Use of the drug in pregnancy and in children <2 years of age requires consideration of potential risks versus benefits. In addition, it is thought that anthelmintics work best in the early stages of the infection; once muscle larvae are established, the clinical effectiveness of anthelmintics is reduced, and larvae can survive for years to cause chronic myalgias. Rapidly destroying larvae with anthelmintics can exacerbate host inflammatory responses and worsen the disease. Corticosteroid therapy, particularly prednisone (30–60 mg/day) for 10 to 15 days is recommended if the diagnosis is secure and the symptoms are severe. Antipyretics and analgesics are used in the myopathic stage and can be continued until fever and allergic signs recede.

Prevention and Medical Ecology

Since 2005, outbreaks of trichinellosis in the US have become rare and sporadic. Generally, most cases have been associated with ingestion of raw or undercooked meats obtained from commercial sources or from wild game. However, pigs raised on family farms, as compared with commercial factory farm operations, are more likely to be fed uncooked garbage and thus acquire the infection.

US Department of Agriculture law, which bans feeding unprocessed garbage, is enforced only in large production facilities. Hunters and those sharing in their kills of carnivorous mammals, including bear, fox, and cougar, have sometimes become infected. Herbivores can harbor the infection because most plant eaters occasionally ingest meat when the opportunity arises. Epidemics caused by eating raw horsemeat have been reported from France, Italy, and Poland.

The scope of meat inspection in the US does not include *Trichinella* spp. In Europe, the countries in the European Union use several strategies for examining meat for muscle larvae. Most of these strategies serve to identify pools of meat sampled from given regions. If these samples consistently test negative, then a *Trichinella*-free designation is applied to that supply of meat. Nonetheless, rare outbreaks occur despite this rigorous system of inspection.

Trichinellosis caused by *T. spiralis* can be prevented by cooking meat thoroughly at 58.5°C for 10 minutes. In the case of pork with viable *T. spiralis* organisms, freezing it at −20°C for 3 days is effective. Freezing is not always effective with meat from other animals or for other species of *Trichinella. T. nativa* was found to survive for up to 34 months in frozen muscles of grizzly bear and for up to 5 years frozen at −18°C in the muscles of carnivores.[67] The freeze tolerance of encapsulated *Trichinella* muscle larvae appears to be largely determined by *Trichinella* spp. but also depends on host tissue.[81–83] Hence thorough cooking is the only way to render all meats safe from all *Trichinella* spp.

Blood and Tissue Nematodes

Filarial Worms

LeAnne M. Fox

Human filariasis, a public health problem of global importance, is caused by infection with threadlike worms that have complex life cycles involving a human host, insect vectors, and in some cases, other mammalian reservoirs. When an infected vector bites or takes a blood meal from a human host, filarial larvae penetrate the skin and migrate to specific tissues, where they develop into sexually mature adult worms. Months after infection, microfilariae are released by the fertile female worm and migrate to the skin or peripheral blood, where they are ingested by an insect vector when it bites or takes a blood meal. Development of the infective third-stage larvae in the insect completes the life cycle. Signs and symptoms of filarial infections are determined in part by the preferred locations of the adult worms and microfilariae (Table 278.1).

The chronic sequelae of filarial infections may not become evident for several years after infection. Infected children living in areas where filariasis is endemic often are asymptomatic. People with no previous exposure who travel to endemic areas tend to have more vigorous immunologic responses to filarial infection, are less likely to have detectable microfilariae, and are more likely to have acute manifestations. For children with an appropriate travel history and signs or symptoms of filariasis or unexplained eosinophilia, the diagnosis can be confirmed by the finding of microfilariae in blood, in skin snips, or on slit-lamp examination of the eye. For *Wuchereria bancrofti*, the most prevalent cause of lymphatic filariasis, assays for circulating parasite antigen are available commercially, but they are not approved by the US Food and Drug Administration.

Determination of serum antifilarial immunoglobulin (Ig) G may be helpful as an initial diagnostic test, particularly in expatriate visitors to endemic areas. This assay is available at the Parasitic

Diseases Laboratory at the National Institutes of Health (phone: 301-496-5398) or at the Centers for Disease Control and Prevention (phone: 404-718-4745). If antifilarial antibodies are not detectable, filarial infection is unlikely. For the patient with antifilarial IgG, a careful clinical and travel history should guide selection of more specific serologic and parasitologic tests for a particular filarial infection.

Many filarial nematodes contain rickettsia-like endosymbiotic bacteria of the genus *Wolbachia* that are important for normal development, viability, and fertility of the adult worm. These bacteria have been investigated as potentially important chemotherapeutic targets and as disease-causing organisms, particularly for lymphatic filariasis and onchocerciasis.

Lymphatic Filariasis

Key Points

Diagnosis and Management of Lymphatic Filariasis

Pathogen

- Filarial nematodes *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*

Epidemiology

- Transmitted through the bite of infected *Aedes*, *Culex*, *Anopheles*, and *Mansonia* species of mosquitoes
- Found in sub-Saharan Africa, southern Asia, the western Pacific Islands, the northeast coast of Brazil, Guyana, Haiti, and the Dominican Republic

Clinical Presentation

- Most infections are asymptomatic.
- Lymphatic dysfunction can lead to lymphedema of the leg, scrotum, penis, arm, or breast years after infection.

- Filarial lymphadenopathy of the inguinal, crural, and axillary lymph nodes is commonly seen in infected children.
- Acute episodes in people with lymphatic dysfunction are associated with painful swelling of an affected limb, fever, or chills due to bacterial superinfection.
- Tropical pulmonary eosinophilia is a potentially serious progressive lung disease that manifests with nocturnal cough, wheezing, and fever in a patient with peripheral blood eosinophilia.

Diagnosis

- Requires epidemiologic risk assessment plus filarial testing
- Microscopic detection of microfilariae on an appropriately timed thick blood film
- Determination of serum antifilarial IgG

Treatment

- Diethylcarbamazine (DEC) is the treatment of choice; drug obtained from the Centers for Disease Control and Prevention is under an investigational new drug protocol.
- Patients with lymphedema and hydrocele can benefit from lymphedema management and, in the case of hydrocele, surgical repair.

Epidemiology

Lymphatic filariasis is caused by three species, *W. bancrofti, Brugia malayi,* and *Brugia timori,* which together infect an estimated 120 million people in Africa, southern Asia, the western Pacific Islands, the northeast coast of Brazil, Guyana, Haiti, and the Dominican Republic (see Table 278.1).[1] More than 90% of these infections are caused by *W. bancrofti.* The three species cause similar signs and symptoms, although genital involvement occurs primarily with *W.*

bancrofti infection.

The adult worms live in the lymphatic vessels for 5 to 10 years. Initial infection, detected as circulating filarial antigen, commonly occurs between the ages of 2 and 4 years.[2,3] In areas of intense transmission, prevalence of microfilaremia increases rapidly between the ages of 5 and 10 years. Chronic manifestations, such as hydrocele and lymphedema, occur infrequently in people younger than 20 years of age and usually increase in frequency with age.[3]

Clinical Manifestations

The clinical expression of lymphatic filariasis varies considerably. Most infected people are asymptomatic. Filarial lymphadenopathy is seen commonly in infected children,[3–5] and before puberty, adult worms can be detected by ultrasonography of the inguinal, crural, and axillary lymph nodes and vessels.[6,7] In boys after puberty, the adult worms tend to live in the intrascrotal lymphatic vessels.[6,7]

Ultrasonography of lymphatic vessels can reveal motile adult worms, called the *filarial dance sign*, examples of which can be viewed on the Internet.[8] Even in asymptomatic people, the presence of living adult worms leads to lymphatic dilation and abnormal lymph flow, which can be demonstrated by lymphoscintigraphy. These changes predispose the person to lymphedema.[9] Lymphatic vessel dilation, lymph node enlargement, and fibrosis can be visualized when lymph nodes are examined histopathologically (Fig. 278.1). Microscopic hematuria and proteinuria also are found.[10]

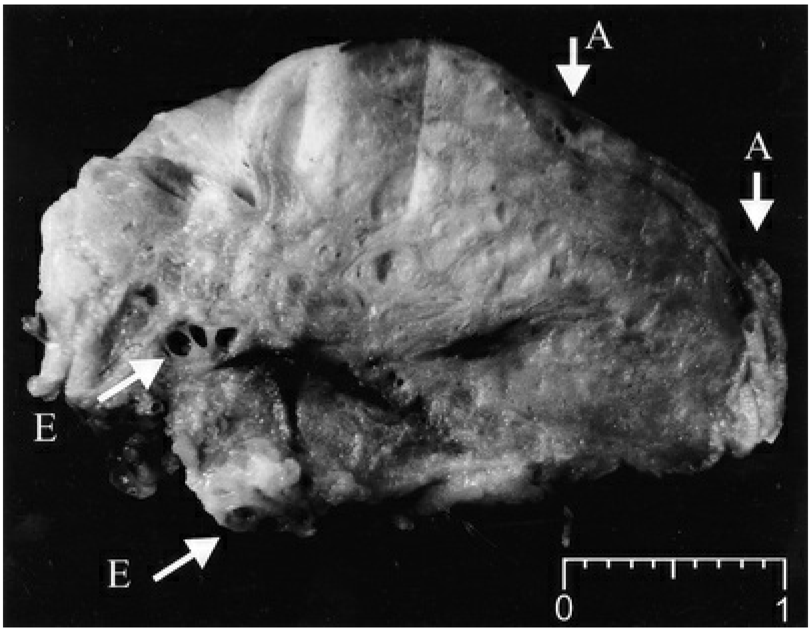

FIGURE 278.1 Gross appearance of a lymph node from a child infected with *W. bancrofti.* The capsule is thickened, and the hilum is distended. Afferent (A) and efferent (E) lymphatic vessels are dilated and tortuous. (From Figueredo-Silva J, Dreyer G. Bancroftian filariasis in children and adolescents: clinical-pathological observations in 22 cases from an endemic area. Ann Trop Med Parasitol 2005;99:759–769.)

Acute filarial lymphangitis has been well documented in travelers to endemic areas. Two to 6 months after exposure, acute inflammation can develop in a lymphatic vessel and its associated lymph nodes, most frequently in the leg, scrotal area, or arm. Characteristically, inflammation progresses distally along the lymphatic vessel, which becomes indurated, tender, and erythematous, and it resolves spontaneously within 3 to 7 days. Because biopsies reveal intense inflammation and nonliving adult worms, acute filarial lymphangitis is thought to be caused by the death of the adult worm.[11]

A separate and clinically distinct syndrome, which for years was confused with filarial lymphangitis, is acute dermatolymphangioadenitis, caused by bacterial infection of the small collecting lymphatic vessels in areas of lymphatic dysfunction.[11,12] Unlike true filarial lymphangitis, this syndrome develops in a reticular rather than a linear pattern and is more commonly associated with severe pain, fever, and chills.

Lymphedema occurs in the legs, scrotum, penis, and arms. In the legs and arms, it usually is unilateral. The most important factor involved in progression of filarial lymphedema to elephantiasis is repeated episodes of acute dermatolymphangioadenitis, originating from breaks in the epidermis, which contribute to further lymph stasis, secondary bacterial infection, and fibrosis.[9]

The pathogenesis of filarial hydrocele is unclear but is thought to be a consequence of lymphatic damage caused by living adult *W. bancrofti*.[9] In filariasis-endemic areas, clinically apparent hydrocele instead may be a chylocele, resulting from rupture of dilated intrascrotal lymphatic vessels and leakage of lymph into the cavity of the testicular tunica vaginalis.[9] Chyluria results from rupture of dilated retroperitoneal lymphatic structures into the renal pelvis.

Tropical pulmonary eosinophilia (TPE) is characterized by peripheral blood eosinophilia (>3000 cells/mm^3), elevated serum IgE (>10,000 ng/mL), low-grade fever, lymphadenopathy, and a nonproductive cough that is more severe at night. Peripheral microfilaremia is absent in patients with TPE. Most cases of TPE have been reported in long-term residents from Asia. Men 20 to 40 years old most commonly are affected, but TPE has been reported in children.

Laboratory Findings and Diagnosis

The standard for diagnosis is microscopic detection of microfilariae on a thick blood film (Fig. 278.2), but filtration of 1 to 5 mL blood through a 0.3- to 0.5-μm nucleopore filter is a more sensitive method.[13] In most endemic areas, the circulation of microfilariae in peripheral blood is periodic, with highest concentrations occurring at night; blood specimens therefore should be collected between 10 PM and 2 AM. Microfilariae of the three species are distinguished morphologically.

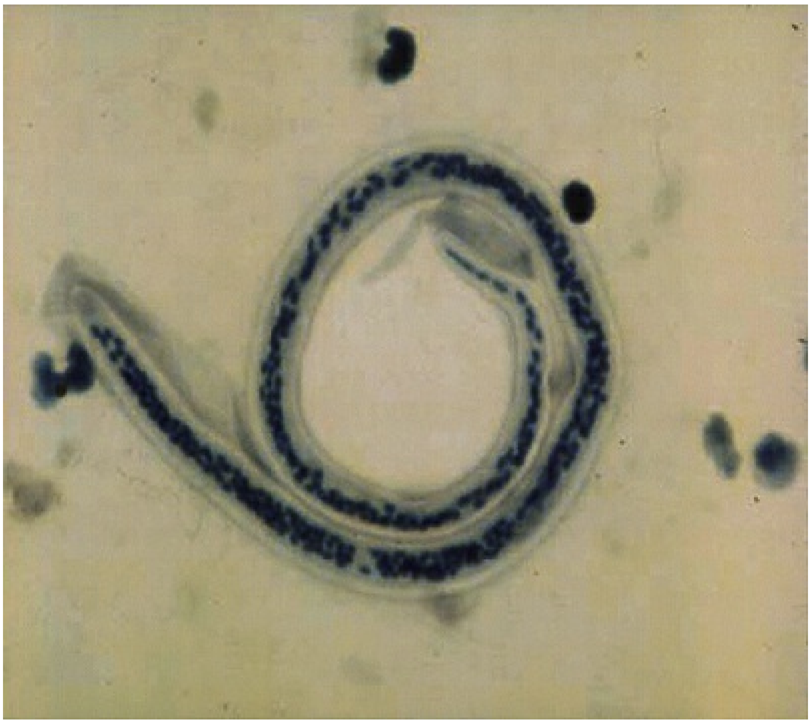

FIGURE 278.2 Microfilaria of *W. bancrofti* on a thick blood film stained with hematoxylin. (Courtesy of Mark L. Eberhard, PhD, Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention, Atlanta, GA.)

Because infected children are frequently microfilaria negative, other tests may be helpful in making the diagnosis. Assays that detect circulating *W. bancrofti* antigen, primarily from the adult worm, may be used, but they are not approved by the US Food and Drug Administration (Table 278.2).[14] Elevated antifilarial IgG4 levels indicate active infection. Ultrasonography can be used to visualize the adult worms in children.[6,7] In postpubertal boys and men, the living adult worms are detected readily on ultrasonography of the scrotal area.[6,7,15] Polymerase chain reaction (PCR) to detect *W. bancrofti* in blood or histopathological specimens may be available in research laboratories.[16]

[a] Elevated if blood is positive for microfilaria or circulating filarial antigen.

[b] Treatment with diethylcarbamazine is given if the patient has specific evidence of filarial infection (i.e., microfilaria or circulating filarial antigen detected or living worms detected on ultrasonography).

[c] Treatment with diethylcarbamazine should be delayed until after the acute episode resolves.

Ig, immunoglobulin; +, positive or detectable; −, negative or nondetectable; +/−, likely positive; −/+, likely negative.

Treatment

Diethylcarbamazine (DEC) is the drug of choice for lymphatic filarial infection. DEC is both microfilaricidal and active against the adult worm. A single 6 mg/kg dose is as effective as the previously recommended dose of 6 mg/kg/day for 12 days for killing the adult worm and long-term suppression of microfilariae.[17]

The severity of systemic adverse reactions to DEC, including fever, myalgia, headache, and malaise, is related directly to microfilarial density before treatment. These symptoms develop within the first 2 days and usually are self-limited. Local adverse reactions, including the formation of tender nodules, can occur at the site of the adult worm, especially in the scrotal area. In the United States, DEC is available only through the Drug Service of the Centers for Disease Control and Prevention (during business hours: 404-718-4745; on evenings, weekends, and holidays: 770-488-7100). DEC is not recommended for treatment during pregnancy, although no teratogenic effects of the drug have been reported.

Ivermectin is a potent microfilaricidal drug but does not kill the adult worm. Ivermectin is therefore not recommended for treatment of the individual affected child, although it has an important role in community-based control programs in Africa. Albendazole appears to enhance the microfilarial suppression of DEC and ivermectin.[18] Initial trials of 4 to 8 weeks of doxycycline, a drug that targets the *Wolbachia* endosymbiont, have suggested activity against *W. bancrofti* adult worms and microfilaria, but more research is needed.[19,20]

Most authorities recommend DEC treatment for infected people regardless of whether they have signs and symptoms of lymphatic filariasis. The goal of treatment is to clear the infection. There is little evidence that DEC alters the course of acute adenolymphangitis or results in clinical improvement of longstanding lymphedema, elephantiasis, or hydrocele. There is one report that suggests that DEC and albendazole can reverse lymphatic pathology in children infected with *B. malayi*.[21] Children with TPE should be treated with DEC to prevent progression to chronic interstitial lung disease. Multiple courses (6 to 8 mg/kg/day for 21 days) may be required. If a clinical response and a decline in eosinophilia are not observed, alternative diagnoses should be considered.

There is growing evidence that lymphedema of the leg can be arrested and potentially reversed by measures such as proper hygiene, skin care, and treatment of skin lesions (e.g., using topical antifungal and antibacterial agents); elevation of the leg and exercise; and in advanced cases, prophylactic antibiotics to prevent secondary infection.[22] Surgical repair is effective for hydrocele, but it often is unsatisfactory for elephantiasis.

Special Considerations

Microfilariae have been observed infrequently in umbilical cord blood of infants born to infected mothers. Children born to infected mothers are more likely to have microfilaremia during childhood than children born to uninfected mothers.[23] It is unknown whether this apparent tolerance to infection is associated with higher or lower risk of disease.

Prevention

Recommendations for personal protection for travelers or visitors to endemic areas include use of insect repellent and bednets, wearing of clothing that covers the arms and legs, and avoidance of outdoor exposure between dusk and dawn. Prophylactic use of DEC has not been evaluated adequately.

In 1997, the World Health Organization launched a global effort to eliminate lymphatic filariasis as a public health problem (http://www.filariasis.org).[24] Recommended interventions include periodic mass treatment with DEC or ivermectin (in combination with albendazole), fortification of household salt with DEC, and vector control. Success in some areas has been demonstrated through surveys whose results have indicated that annual mass drug administration can be interrupted.[25]

Onchocerciasis

Key Points

Diagnosis and Management of Onchocerciasis

Pathogen

- Filarial nematode *Onchocerca volvulus*

Epidemiology

- Transmitted through female blackflies (genus *Simulium*), which bite during the day and breed near rapidly flowing rivers and streams
- Found in sub-Saharan Africa, with endemic foci in Yemen, Brazil, and Venezuela

Clinical Presentation

- Symptoms begin after patent infections are established, which may take 18 months.
- Symptoms include highly pruritic and papular dermatitis, subcutaneous nodules called *onchocercomas*, lymphadenitis, and ocular lesions, which can progress to visual loss and blindness.

Diagnosis

- Requires epidemiologic risk assessment plus filarial testing
- Microscopic detection of microfilariae in superficial skin shavings or punch biopsy, adult worms in histologic sections of excised nodules, or characteristic eye lesions
- Determination of serum antifilarial IgG is most useful when microfilariae are not identifiable.

Treatment

- Ivermectin is the treatment of choice; repeated annual or semiannual doses may be required.
- Coinfection with *Loa loa* should be excluded before onchocerciasis treatment with ivermectin.
- Some experts recommend a 6-week course of doxycycline to kill *Wolbachia* organisms, which appear to be required for the survival of *O. volvulus*. This approach may be used as adjunctive therapy for children 8 years or older.
- Diethylcarbamazine (DEC) is contraindicated in onchocerciasis because it has been associated with severe and fatal posttreatment reactions.

Onchocerciasis, a leading cause of blindness worldwide, results from infection with *Onchocerca volvulus.* The infection is transmitted by blackflies of the genus *Simulium,* which breed near flowing water; hence the name *river blindness*. An estimated 37 million people worldwide are infected. The disease is most prevalent in sub-Saharan Africa, and endemic foci are found in Yemen, Brazil, and Venezuela.

In humans, the infective larvae mature in the subcutaneous and deeper connective tissues. Several adult worms of both sexes coil together and form fibrous nodules 1 to 2 cm in diameter, which are most noticeable over bony prominences, including the skull (Fig. 278.3). Adult females can live for 12 to 15 years and produce millions of microfilariae. The microfilariae, which are responsible for the signs and symptoms of onchocerciasis, migrate from the nodule to skin and connective tissues.

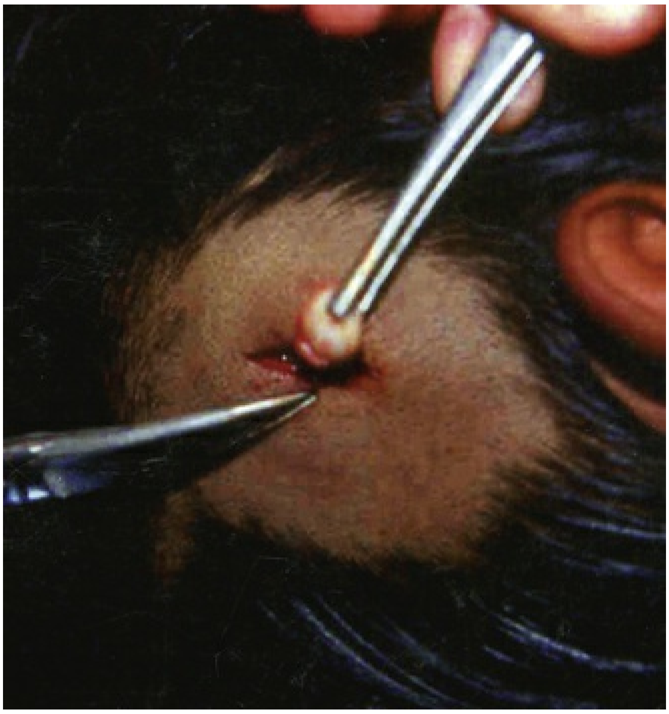

FIGURE 278.3 An onchocercal nodule is removed from the head of a child. (Courtesy of Frank O. Richards MD, The Carter Center, Atlanta, GA.)

Epidemiology

The prevalence of infection increases dramatically during childhood. In hyperendemic areas of West Africa, for example, microfilariae can be detected in the skin of 1% to 2% of children 5 years of age or younger and in approximately 90% of children 15 years of age.[26] Transplacental infection of microfilariae has been documented. Blindness is rare in young children, but impaired vision due to onchocerciasis begins to occur by the second decade of life.

Clinical Manifestations

In addition to subcutaneous nodules, called *onchocercomas*, the major clinical manifestations of onchocerciasis are dermatitis, lymphadenitis, and ocular disease. Inflammation surrounding dead microfilariae in the skin gives rise to pruritus, a common early symptom of onchocerciasis in children. Pruritic dermatitis characterized by epidermal atrophy and loss of pigment can develop in older children with high microfilarial density.

Ocular disease is the most serious complication of *O. volvulus* infection, but it is less common in people with brief exposures or light infections. Inflammation associated with death of microfilariae in the cornea causes punctate keratitis, an early ocular lesion commonly found in infected children. The lesion seems to resolve without intervention. Usually after years of exposure, vision loss and blindness can result from sclerotic keratitis, anterior uveitis, chorioretinopathy, or optic nerve atrophy.

Laboratory Findings and Diagnosis

Demonstration of microfilariae in the skin is the standard for diagnosis, although microfilariae often are not detectable in infected North American travelers returning from endemic areas. Skin snips are obtained with a sclerocorneal biopsy punch or by elevating a small cone (3 mm in diameter) of skin with a needle or straight pin and shaving it off bloodlessly with a scalpel or razor blade. The skin snip is then incubated in saline at room temperature for 30 minutes to 24 hours to allow emergence of the microfilariae, which can be visualized microscopically.[13]

The diagnosis of onchocerciasis also can be made through excision of subcutaneous nodules and identification of the adult worms. Ultrasonography may be helpful in detecting impalpable nodules.[27] Microfilariae in the anterior chamber of the eye are detected readily on slit-lamp examination. The chances of detection are increased if patients are asked to sit with the head between their legs for up to 10 minutes before the examination. Microfilariae also can be observed in the cornea, vitreous, and retrolental space.

As in lymphatic filariasis, measurement of total antifilarial IgG and IgG subclasses can be useful diagnostically, particularly when microfilaria are not identifiable. Determination of serum antifilarial IgG is available at the Parasitic Diseases Laboratory at the National Institutes of Health (phone: 301-496-5398) or at the Centers for Disease Control and Prevention (phone: 404-718-4745). Assays to detect specific antibodies to *Onchocerca* and PCR assays to detect onchocercal DNA in skin snips are available in specialized laboratories.[28,29]

Treatment

Ivermectin is the drug of choice for treatment of onchocerciasis. Ivermectin is available commercially in the United States, but it is not approved for use in children weighing less than 15 kg, pregnant women, and mothers nursing infants during the first week of life.

Ivermectin is given in a single dose of 150 µg/kg on an empty stomach. Microfilarial densities in the skin are reduced by 85% to 95% at 2 months after a single dose; ocular microfilarial densities decline more slowly. Unlike DEC, which formerly was used to treat onchocerciasis, ivermectin causes few adverse ocular reactions. A mild Mazzotti reaction, which is associated with the death of microfilariae and characterized by pruritus, a maculopapular rash, fever, edema, and headache, can occur in 10% to 20% of patients after treatment. DEC is contraindicated in onchocerciasis because it has been associated with severe and fatal posttreatment reactions.

Patients coinfected with onchocerciasis and loiasis can develop encephalopathy when treated with ivermectin, and it is recommended that coinfection with *Loa loa* be excluded before onchocerciasis treatment with ivermectin.[30] Ivermectin improves the pruritus and rash associated with onchocercal dermatitis and seems to reverse early disease in the anterior segment of the eye. However, it appears to be less effective in reversing chronic skin depigmentation or posterior ocular disease.

Although ivermectin interferes with release of microfilariae from the uterus of the adult female, the drug does not kill the adult worm. Repeated single doses of ivermectin are required, usually at 6- to 12-month intervals, particularly for people with ocular disease. All people with a diagnosis of onchocerciasis should undergo slit-lamp examination to assess the extent of ocular involvement. Expert ophthalmologic advice should be sought before treating eye lesions.

Antibiotic trials with doxycycline directed against *Wolbachia,* an endosymbiotic bacteria found in *O. volvulus,* have demonstrated decrease in onchocercal microfilaridermia with 6 weeks of therapy and macrofilaricidal activity when given with a single standard dose of ivermectin. Further trials, including those with shorter lengths of therapy, are needed.[31,32]

Prevention

To reduce exposure to blackflies, travelers should avoid blackfly habitats (i.e., free-flowing rivers and streams) and use insect repellent or wear protective clothing, particularly during the morning and evening, when the insects' biting activity is greatest. Individual prophylactic use of ivermectin has not been evaluated.

Loiasis

Key Points

Diagnosis and Management of Loiasis

Pathogen

- Filarial nematode *Loa loa*

Epidemiology

- Transmitted by the bite of the deerfly *(Chrysops)*
- Found in West and Central Africa

Clinical Presentation

- Symptoms vary from asymptomatic infection to life-threatening complications, including encephalopathy, cardiomyopathy, and renal disease.
- Clinical signs and symptoms are different for visitors and infected residents because of different immune responses to the parasite.

Visitors often have Calabar swellings, whereas infected residents report subconjunctival migration of the worm across the eye.

Diagnosis

- Requires epidemiologic risk assessment plus filarial testing
- Microscopic detection of microfilariae in blood smears obtained at midday (10 AM–2 PM) or identification of an adult *L. loa* worm removed from subcutaneous tissue or the conjunctiva of the eye
- Determination of serum antifilarial IgG is most useful when microfilariae are not identifiable.

Treatment

- Diethylcarbamazine (DEC) is the treatment of choice.
- Severe adverse reactions, including encephalopathy, are related to microfilarial density before treatment, and patients may require plasmapheresis to reduce microfilariae before initiation of DEC.
- DEC should not be used in patients with concomitant onchocerciasis because of the risk of severe Mazzotti reactions.
- Ivermectin has been associated with encephalopathy in people with high *L. loa* microfilarial counts who are coinfected with *L. loa* and *O. volvulus*, and it is not recommended for the treatment of loiasis.

Loa loa infection occurs in West and Central Africa and is transmitted by the bite of the deerfly *Chrysops*. The adult worms, which have a lifespan of up to 17 years, wander through the subcutaneous tissues and sometimes beneath the conjunctiva. Microfilariae circulate in the peripheral blood with a diurnal periodicity. Peak microfilarial density occurs around noon.

Epidemiology

Microfilarial prevalence and density increase throughout childhood. Microfilaremia has been reported in a few neonates, but most studies have found no evidence for transplacental transfer of microfilariae or microfilarial antigen. In areas of intense transmission, the prevalence of microfilaremia can reach 35% in adults, but the prevalence of infection probably is higher because 14% to 67% of persons with documented *L. loa* infection have no detectable microfilaremia.

Clinical Manifestations

The clinical manifestations of loiasis vary from asymptomatic infection to life-threatening complications, including encephalopathy, cardiomyopathy, and renal disease. Clinical signs and symptoms are different for visitors to or temporary residents of loiasis-endemic areas and the children born and raised in these areas because of different immune responses to the parasite.[33]

Temporary residents often have no detectable microfilaremia; they are more likely to have Calabar swellings, which are transient (up to several days' duration) pruritic areas of nontender erythematous angioedema that are several centimeters in diameter. These lesions typically occur on the extremities, such as the wrist or knee, and are thought to be associated with migration of the adult worm. In contrast, infected residents of endemic areas frequently have microfilariae in blood and commonly report subconjunctival migration of the worm across the eye, which can be accompanied by intense conjunctivitis and swelling of the eyelid.

Laboratory Findings and Diagnosis

The diagnosis can be confirmed through detection of microfilariae in peripheral blood obtained during the day or by identification of an adult *L. loa* worm removed from subcutaneous tissue or the conjunctiva of the eye. In expatriates, hypereosinophilia (>3000 cells/mm^3) is common, and serum IgE and antifilarial antibody titers are elevated.[34] A PCR test has been described, but it is available only in research settings.[35]

Treatment

Because DEC is active against the microfilariae and adult worms, it is the drug of choice for loiasis (8 to 10 mg/kg/day in 3 divided doses for 21 days), although several courses may be required for successful treatment.[36] Severe adverse reactions, including encephalopathy, are related to microfilarial density before treatment, but reactions also can occur in people with moderate microfilaria levels (>2000 microfilariae per milliliter of blood). Neither a gradual increase in DEC dose nor pretreatment with corticosteroids is completely effective in preventing encephalitis in such patients. Patients should be monitored closely during initiation of treatment and may require hospitalization.

Plasmapheresis has been used to reduce the microfilarial load in people with high numbers of circulating microfilariae before initiation of DEC and corticosteroid therapy. DEC should not be used in patients with concomitant onchocerciasis because of the risk of severe Mazzotti reactions, characterized by an intense pruritic rash, fever, hypotension, and possibly ocular damage (in those with microfilariae in the eyes).

Ivermectin reduces microfilarial density but does not appear to kill the adult worm. Ivermectin has been associated with encephalopathy in people with high *L. loa* microfilarial counts (>30,000 microfilariae/mL) who are coinfected with *L. loa* and *O. volvulus,* and it is not recommended for the treatment of loiasis.[30] Preliminary observations indicate that albendazole may kill the adult stage of the parasite.[37] There is no evidence for *Wolbachia* endosymbiosis with *L. loa.*[38]

Prevention

Personal protection measures are recommended to prevent deerfly bites. A study of Peace Corps volunteers in West Africa suggested that DEC (300 mg once weekly) could be taken prophylactically to reduce the risk of infection.[39]

Other Causes of Filariasis

Mansonella streptocerca.

Mansonella streptocerca is transmitted by midges and is found in West and Central Africa. Adult worms live in the dermis and subcutaneous tissues. Microfilariae are found in the skin and can be diagnosed from skin snips or biopsies. Signs and symptoms include hypopigmented macular lesions over the thorax, pruritic dermatitis, and lymphadenopathy; asymptomatic infection is common.

Treatment with DEC (6 mg/kg/day for 21 days) kills adult worms and microfilariae. Ivermectin is effective against the microfilariae.[40] Both drugs can produce Mazzotti reactions.

Mansonella perstans.

Mansonella perstans is transmitted by midges in sub-Saharan Africa, in Central and South America, and in focal areas of Algeria and Tunisia. The adult worms, which rarely are recovered, live in the peritoneal, pericardial, and pleural cavities and in associated connective tissue; microfilariae appear in the blood. The prevalence of microfilaremia rises with age. Infection has been reported in children as young as 2 years.

Most people with microfilaremia are asymptomatic, but a variety of symptoms have been associated with infection, including arthralgias, pruritus, conjunctival granulomas, periorbital edema, angioedema similar to Calabar swellings, and rarely, pericarditis. The diagnosis is made through detection of microfilariae in the blood. Eosinophilia and coinfection with *L. loa, W. bancrofti,* or *O. volvulus* are common findings.

Although chronic sequelae are poorly defined, treatment is recommended. Mebendazole (adult dose: 100 mg twice daily for 14 to 21 days), alone or in combination with DEC, appears to be more effective than DEC alone in clearing *M. perstans* microfilaremia.[41] Albendazole may be of value when given at a dose of 400 mg twice daily for at least 1 month. A trial demonstrated that doxycycline (200 mg daily for 6 weeks) is effective.[42] Repeated courses of DEC (6 mg/kg/day for 14 to 21 days) may not be effective, and ivermectin has not proved effective. Adverse reactions are similar to those associated with treatment of other filarial infections and are related to microfilarial levels. There is evidence for *Wolbachia* endosymbiosis in at least some isolates of *M. perstans.*[43]

Mansonella ozzardi.

Mansonella ozzardi is transmitted by midges and blackflies in the Caribbean and Central and South America. Adult *M. ozzardi* live in serous cavities, particularly the thoracic and peritoneal cavities, and in connective and subcutaneous tissues. Most infected people are asymptomatic, although infection has been associated with arthralgia, pruritus, adenopathy, keratitis, and vague constitutional symptoms. Eosinophilia is a common finding.

Little is known about the epidemiology of *M. ozzardi* infection in children. Diagnosis is made through detection of microfilariae in blood or skin snips. A single 150-μg/kg dose of ivermectin reduces microfilaremia.[44] Treatment with DEC or albendazole is ineffective.

Dirofilariasis

Pulmonary dirofilariasis in adult humans is caused by infection with *Dirofilaria immitis,* the agent of canine heartworm disease. The parasite is transmitted by mosquitoes. In humans, the worms migrate to the right ventricle of the heart, enter the pulmonary arteries, are carried to the periphery of the lung, and degenerate or calcify, causing solitary pulmonary nodules that classically appear as *coin lesions* on chest radiographs. They are unable to complete maturation in the human host.

Although most affected people are asymptomatic, some experience cough, hemoptysis, or chest pain. Eosinophilia occurs in less than 15% of cases. Microfilaremia has not been observed in humans. The diagnosis is made by biopsy of the lung lesion and histologic examination. Although serologic tests are available, their sensitivity and specificity are not adequate for the diagnosis of human dirofilariasis. Antifilarial treatment is not necessary.

Subcutaneous dirofilariasis is caused by infection with *Dirofilaria tenuis,* which lives in the subcutaneous tissues of the raccoon, and *Dirofilaria repens,* which lives in the subcutaneous tissues of dogs and cats. In humans, the adult worms cause subcutaneous granulomas in the conjunctiva, eyelid, oral mucosa, extremities, scrotum, breast, and other tissues. These nodules can be tender, painful, and erythematous. Microfilaremia does not occur. The lesions can be excised surgically to confirm the diagnosis.

Diphyllobothrium Species

Description of the Pathogen.

Pseudophyllidean cestodes of the genus *Diphyllobothrium* can cause intestinal tapeworm infections in humans. Among more than 50 species of *Diphyllobothrium*, 14 are known to infect humans. Adult tapeworms develop in mammals or birds, and infection usually is contracted by eating raw or undercooked fish. First-stage larvae are found in crustaceans, and second-stage larvae develop in fish, although for some *Diphyllobothrium* species, the second intermediate host is unknown.

Diphyllobothrium latum (also known as fish or broad tapeworm) is the best-known species infecting humans. Other primarily zoonotic tapeworms that can cause human infection include *D. nihonkaiense, D. dendriticum, D. cordatum, D. dalliae, D. lanceolatum, D. pacificum,* and *D. ursi*.[1,2] However, only *D. latum* has the ability to compete with its host for vitamin B_{12} and place the patient at risk for megaloblastic anemia.

The *Diphyllobothrium* adult-stage tapeworm attaches to the small intestinal mucosa with two sucking grooves (i.e., bothria) located on the ventral and dorsal surfaces of the scolex (i.e., head). The body (i.e., strobila) of the tapeworm can reach up to the amazing length of 12 m. The strobila is composed of thousands of proglottid segments, which break off the distal end of the worm and are passed singly or in chains during defecation. Each proglottid contains thousands of eggs, some of which can be released into feces during passage through the intestinal tract. Feces must be deposited promptly into fresh or salt water for an egg to hatch and release a free-swimming embryo (i.e., coracidium).

The coracidium is ingested by copepods (including *Cyclops* and *Diaptomus* species), enters the body cavity and develops into the first-stage larva (i.e., procercoid). If the copepod is ingested by plankton-eating fish, the second-stage plerocercoid larva develops in the muscles. The size and shape of this larva can help to identify the infecting species of *Diphyllobothrium.* Depending on the parasite species, freshwater, anadromous, or marine fish are the second intermediate hosts. The second intermediate hosts for *D. latum* are freshwater fish such as trout, pike, turbot, and perch; *D. nihonkaiense* is found in salmon species in the Pacific Ocean; *D. pacificum* is found in marine fish from the Pacific coast of South America, and larvae of *D. dendriticum* have been reported in Atlantic salmon and whitefish.

The plerocercoid develops into the adult intestinal tapeworm after the infected fish is ingested by an appropriate mammalian or avian host, which for *D. latum* includes humans, dogs, cats, foxes, bears, and pigs. *D. nihonkaiense* is found in the brown bear and humans, and *D. pacificum* is found in sea lions, seals, and occasionally in humans. *D. dendriticum* can use seagulls and mammals as its definitive host.[1,2]

Epidemiology.

Diphyllobothriasis occurs worldwide and is primarily an infection of older children and adults, although infection of a 2-year old child with *D. nihonkaiense* has been reported.[3] Infection is most prevalent in populations whose culinary habits result in consumption of raw or undercooked fish flesh, liver, or roe.

Development of molecular tools to identify the species of *Diphyllobothrium* causing human infections provided insights into the epidemiology of this disease. In the past, most infections were attributed to *D. latum,* but later information implicated other species based on species-specific second host preferences and geographic distribution as defined by polymerase chain reaction (PCR) studies.[1,2,4,5] *D. latum* infections are most prevalent in the temperate and subarctic zones of Eurasia, particularly Finland, Sweden, and Lithuania. *D. latum* and other *Diphyllobothrium* species occur in other populations of Europe (especially northern Italy, Romania, the lower Volga, and the Baltic nations), in Eskimos in Alaska and Canada, and in Latin America.

Cases of *D. pacificum* infection have been reported in Peru, Chile, and Argentina.[1] *D. dendriticum* is found in regions farther north than *D. latum*; most infections in polar regions are likely caused by this species. Most human infections in Asia (Japan, Siberia, and Manchuria) are caused by *D. nihonkaiense*.[1] In the United States, infected salmon was implicated in 82% of 52 cases on the West Coast[6]; these infections were most likely associated with *D. nihonkaiense* given the preference for that species to parasitize Pacific salmon.[7] Fish from the Great Lakes region also have been implicated, although cases of diphyllobothriasis have been less frequently reported from this focus in recent years.[2]

Because "fresh" fish are shipped nationally and internationally, the risk associated with consuming certain fish dishes (e.g., sushi, ceviche, lightly pickled fish, smoked fish, gefilte fish) is widespread, and human infections may be associated with nonnative species of *Diphyllobothrium*.[8–10] *Diphyllobothrium* spp. can be introduced into new regions as a result of aquaculture; one example is the possible introduction of *D. latum* to lakes in South America by means of plerocercoid infection in food fish species.[11]

Clinical Manifestations.

Few pathologic changes are observed in the intestinal mucosa of animals with diphyllobothriasis, and most infected people are asymptomatic. In a study in eastern Finland, 37% of the 295 tapeworm carriers had symptoms (vs. 8% of 832 controls) that included diarrhea, fatigue, change in appetite, and paresthesias; younger persons were less likely to have symptoms.[1] Abdominal pain, nausea, and diarrhea occurred in 2 of 4 cases of diphyllobothriasis in a US outbreak associated with salmon sushi.[12]

Parts of the strobila can be passed in stool or vomitus, but proglottids are not very motile and do not spontaneously exit the anus, as can proglottids of the beef tapeworm *Taenia saginata.* Intestinal obstruction can occur when multiple worms are present. Megaloblastic anemia resulting from vitamin B_{12} deficiency is reported to occur in up to 2% of *D. latum*–infected Scandinavian adults. Pallor, fatigue, glossitis, decreased vibration sense, paresthesia, and central scotoma have been described as clinical features in these patients.[13]

Laboratory Findings and Diagnosis.

Mild eosinophilia of 5% to 15% can occur. Intestinal diphyllobothriasis is diagnosed by finding typical eggs in feces 5 or more weeks after ingestion of infected fish. Because egg discharge is periodic in intestinal diphyllobothriasis, the diagnosis can be missed by examining a single stool sample. Eggs are light yellow, operculated, and ovoid, with dimensions ranging from 40 to 80 μm. The microscopist may confuse *Diphyllobothrium* eggs with other operculated eggs produced by flukes of the several genera, including *Clonorchis, Fasciola, Nanophyetus,* and *Paragonimus*.

The proglottids have a fleshy consistency and are ivory in color (sometimes with central darkening). They are wider (12 mm) than they are long (4 mm). The appearance of these broad proglottids suggests the diagnosis of diphyllobothriasis, but a species diagnosis is difficult, even when the proglottids and scolex are recovered and submitted to experts for examination. Although megaloblastic anemia is rare, up to 50% of tapeworm carriers in Finland have reduced serum vitamin B_{12} levels.[13]

Treatment.

For intestinal infections, single-dose therapy with praziquantel (5 to 10 mg/kg) is highly efficacious (i.e., 85% to 95% cure rate); purgatives are not necessary. Niclosamide also is effective as a single dose, but it is no longer available in the United States. Stool examinations to evaluate for cure may be performed 6 or more weeks after therapy. Cobalamin injections and oral folic acid are indicated for patients with clinical or laboratory evidence of vitamin B_{12} deficiency.

Prevention.

Preventing *Diphyllobothrium* infection in humans depends on altering food handling and eating habits because regulations for proper disposal of human feces alone have no impact on contamination of water supplies with eggs from animal sources. Cooking fish to an internal temperature of at least 63°C is recommended. Freezing at −35°C or below and storing at −20°C for 24 hours kills plerocercoids and renders the meat safe for consumption. Canned fish is safe, but smoked fish is safe only if the fish was frozen appropriately before smoking to kill any parasites.[14] Although diphyllobothriasis is not transmitted from person to person, more than one family member can be infected by sharing common meals and having similar eating habits.

Dipylidium caninum

Description of the Pathogen.

Dipylidium caninum (dog tapeworm or double-pored tapeworm) is a common intestinal cestode of domestic dogs and cats that can infect children who ingest fleas. The scolex of the adult worm has four suckers and is armed with up to seven rows of hooklets. The 15- to 70-cm tapeworm chain (i.e., strobila) consists of about 150 proglottids. The proglottids, which are highly motile, are passed whole in feces and easily observed in stool; they later disintegrate in soil to release their eggs. The eggs develop into cysticercoid larvae only if they are consumed by the larval stage fleas. The life cycle is completed when an infected flea is ingested by a dog or cat during its grooming activities.[15]

Epidemiology.

Young children can become infected if they swallow fleas while playing with their pets or when crawling in flea-infested areas. From 1973 to 1977, a period when the Centers for Disease Control and Prevention (CDC) was the only source of the drug niclosamide in the United States, about 8 cases were reported per year.[16] The introduction of effective flea control and prevention and certain monthly deworming treatments for dogs and cats probably helped to reduce the prevalence of *D. caninum* infection in some areas.[17]

Clinical Manifestations.

Parents usually find proglottids as multiple, motile, white objects resembling rice or seeds (often described as cucumber, melon, or pumpkin seeds) in stool or diapers or on the perineum (Fig. 279.1A).[18] The child usually is asymptomatic, although anogenital pruritus, rash, irritability, diarrhea, and abdominal pain have been described. Older children can complain of spontaneously passing proglottids per anus. A history of dog or cat pets, fleas, and flea bites are important clues to the diagnosis.

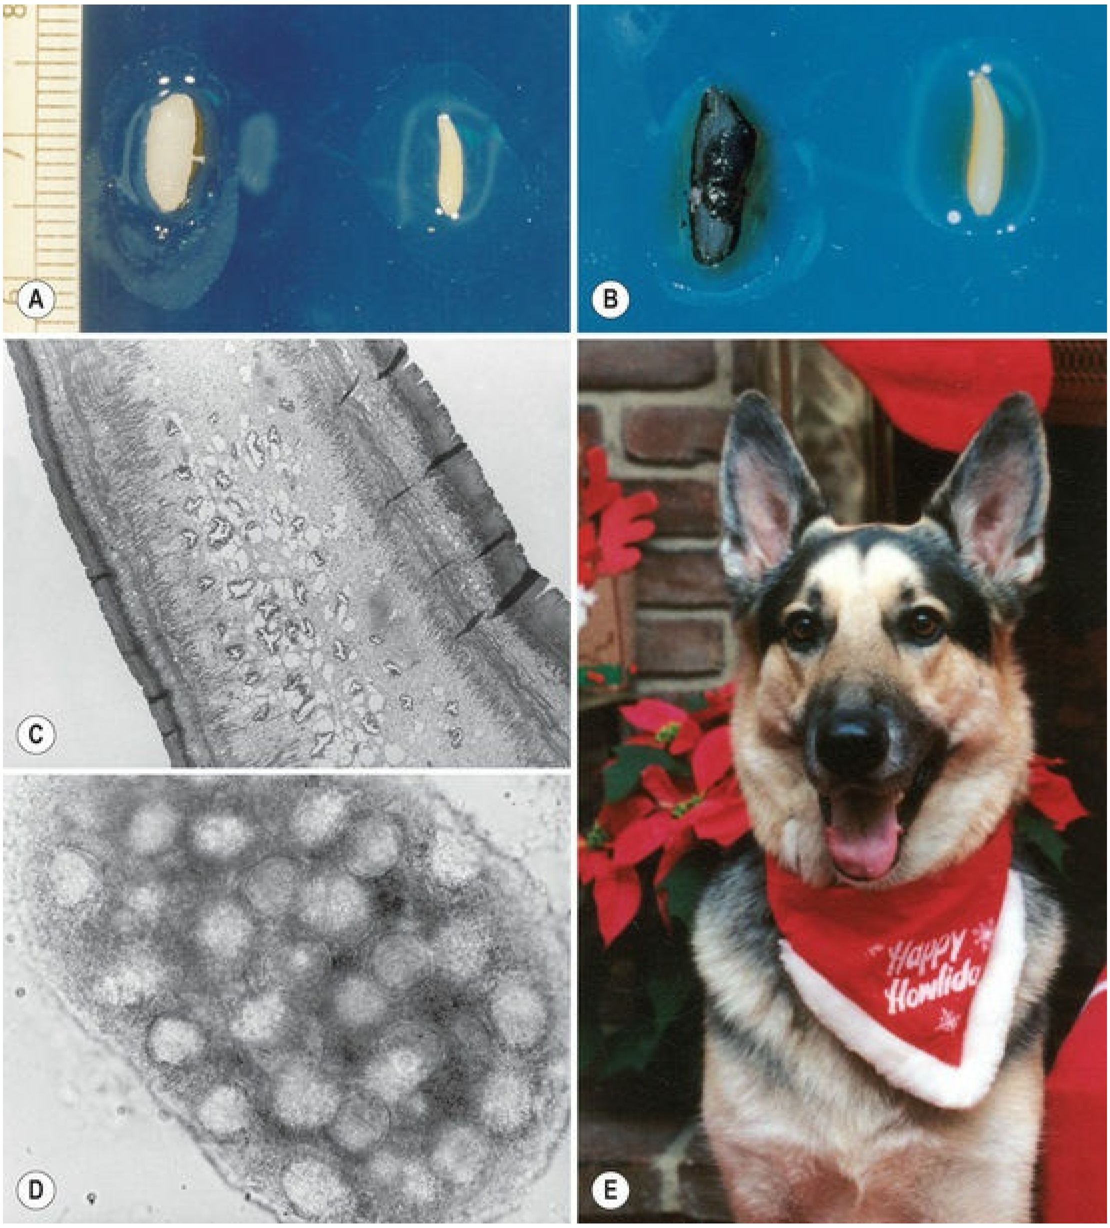

FIGURE 279.1 A 20-month-old girl was seen in consultation because of “moving rice” in the stool on the diaper. The *Dipylidium caninum* body consists of

proglottid segments, which contain the tapeworm's microscopic eggs. The motile, white proglottids resemble rice grains and are easily observed in stool. Laboratory Findings and Diagnosis.

The differential diagnosis includes enterobiasis (i.e., pinworm) and intestinal myiasis (fly larvae). Parents should be advised to place the proglottids in rubbing alcohol to preserve their differential characteristics for diagnosis. Grossly, a gravid *D. caninum* proglottid measures 3 to 4 mm wide and 10 to 12 mm long. It is narrowed at both ends and has two lateral indentations (indicating pores) at its longitudinal midpoint (see Fig. 279.1B). Microscopic stool examinations usually are negative because few eggs are released from proglottids into the fecal stream. However, characteristic egg packets (i.e., loose membrane usually containing 8 to 63 eggs and measuring 120 to 200 μm long) can be identified in stool or on perianal adhesive tape (paddle) preparations (see Fig. 279.1D).[15,18]

Treatment.

Single-dose therapy with praziquantel (5 to 10 mg/kg) is the recommended therapy. Praziquantel is not approved for the treatment of children younger than 4 years of age, but it has been used successfully to treat cases of *D. caninum* infection in children as young as 6 months.[18–20] Niclosamide is effective but is not available in the United States.

No purge or follow-up stool examination is indicated, but the appearance of proglottids after therapy is indication for retreatment. The infection is self-limited in the human host and typically clears spontaneously by 6 weeks.

Prevention.

Periodic deworming of pets controls this and other canine and feline helminthic infections of pediatric concern, including *Toxocara* species and dog and cat hookworm. Flea control also is important. Examination of asymptomatic family members rarely is indicated.

Hymenolepis nana and *Hymenolepis diminuta*

Description of the Pathogen.

Human hymenolepiasis is caused by *Hymenolepis nana* (i.e., dwarf tapeworm) or rarely by *Hymenolepis diminuta* (rodent tapeworm). The complex life cycles of these cestodes consist of adult (tapeworm) stages in the small bowel of humans and rodents, and larval (cysticercoid) tissue stages in insects. The cysticercoid stages of *H. nana* also can invade and develop in the human intestine; as a result, *H. nana* can complete its entire life cycle in the human host and, through autoinfection, increase its numbers without having to pass through the insect host. Animal studies demonstrate that T-lymphocyte–mediated immunity is important in preventing hyperinfection by these parasites.[21,22]

H. nana usually is acquired by ingestion of eggs, the hexacanth embryos of which invade the villi of the small intestine. Within 4 to 6 days, the embryo develops into a cysticercoid larva that re-enters the lumen, evaginates to become the scolex of the tapeworm, and attaches to the mucosal wall. Morphologically, the scolex has four suckers and numerous hooklets. A strobila measuring 0.5 to 4.5 cm long and 1 mm wide develops behind the scolex in about 2 weeks. The strobila consists of proglottid segments that periodically break off and rapidly degenerate to release their eggs into the fecal stream.

Unlike all other tapeworms that infect humans, *H. nana* eggs are infectious immediately when passed. In addition to being a risk to others, infected people may reingest their own eggs by fecal-hand-mouth transfer (i.e., external autoinfection), or eggs may hatch in the intestine, reinvade, and develop into new worms (i.e., internal autoinfection). A variety of insects that consume feces support development of *H. nana* cysticercoids in their body cavities. Ingestion of these insects by humans or rodents is another route of infection.

The *H. diminuta* tapeworm is much larger than *H. nana* and measures 10 to 60 cm long and 2 to 4 mm wide. Completion of the life cycle of *H. diminuta* depends on development of the cysticercoid stage in the body cavities of insects that ingest eggs they find in rodent feces; autoinfection does not occur. Most commonly minute flour, grain, or dung beetles, fleas, and cockroaches serve as intermediate hosts. Rodents and rarely humans acquire the intestinal stage by consuming uncooked corn, flour, cereal, grains, and dried fruit contaminated with infected insects.

Epidemiology.

H. nana is the most common cestode infecting children, with a prevalence ranging from 0.1% to 50%. The highest rates occur among school-aged children in hot, arid areas of the developing world.[21] Changes in hygienic habits and immunity make *H. nana* infections less common in adults. *H. nana* infections usually are transmitted through fecal-oral contact. In 1987, diagnostic laboratories in the United States found *H. nana* eggs in 0.4% of 216,000 stool specimens[23]; however, infection rates in orphanages and institutions were as much as 10 times higher.[24]

Undefined host factors are important. In a 22-month longitudinal study in Pakistan, one third of children with similar exposure risks were never infected, one third were infected intermittently, and one third were always infected.[25] *H. diminuta* infections tend to occur in conditions in which rodents and insects have access to grain stores.

Clinical Manifestations.

The intensity of infection (i.e., worm burden) is the major determinant of symptoms. Patients whose egg density in stool is greater than 15,000/g invariably have abdominal cramps, diarrhea, and irritability.[26] In light infections, patients are asymptomatic. Based on uncontrolled studies, some investigators have suggested that *H. nana* toxins can cause seizures or conjunctivitis. *H. diminuta* infections usually are asymptomatic.[21]

Laboratory Findings and Diagnosis.

Mild to moderate eosinophilia is an inconsistent finding, and serologic tests are not available. The diagnosis most often is made by finding characteristic eggs in stool. The *H. nana* egg is oval, is 37 to 47 µm in diameter, and has a double-layered shell that encloses characteristic filaments arising from bipolar thickenings. The enclosed embryo contains 6 hooklets. *H. diminuta* eggs are larger and rounder (60 to 85 µm in diameter) and have no polar filaments.

Fecal concentration techniques that examine larger amounts of stool are preferred to direct fecal smears. *H. nana* eggs can disintegrate if the specimen is not examined promptly or preserved in formalin. Three stool examinations performed on alternate days are necessary to exclude a suspected infection. The proglottids disintegrate rapidly during their intestinal transit and usually are not observed in feces.

Treatment.

A single dose of praziquantel (25 mg/kg) cures 95% to 100% of *H. nana* and *H. diminuta* infections and is the preferred treatment.[21,27] Niclosamide, which is not available in the United States, is not effective as a single dose and must be given daily for several days.[16] Repeat stool examinations are recommended 4 weeks after therapy to document cure. Light burden infections have been successfully treated with nitazoxanide.[27,28]

Special Considerations.

Family members of patients infected with *H. nana*, particularly siblings, should have stools examined. Simultaneous chemotherapy for people in institutions and for family members may be indicated in some circumstances. Up to 11% of Cambodian refugee children have had *H. nana* infections.[29] Few examples of *H. nana* dissemination in immunosuppressed humans have been reported, but disseminated disease has not been reported in people infected with human immunodeficiency virus (HIV) who live in *H. nana*-endemic areas.[21,30,31]

Prevention.

Transmission of *H. nana* can be controlled by measures that decrease fecal-oral contact, particularly hand hygiene after defecation and diaper changing. Hand hygiene after handling pet rodents is advised. Infected food handlers should be treated and cure verified by repeat stool examinations. Rodent and insect control are important, and corn, grain, flour, cereal, and dried fruit stores should be sealed.

Taenia solium, *Taenia asiatica*, and *Taenia saginata*

Taeniasis and Cysticercosis

Natalie J.M. Dailey Garnes, A. Clinton White Jr., Jose A. Serpa

Clinical syndromes associated with infection with *Taenia* species tapeworms include intestinal disease caused by adult parasites (i.e., taeniasis) and single or multiorgan inflammatory conditions associated with larval stages within tissue (i.e., cysticercosis and coenurosis).[1–3] Distinguishing morphologic features of adult tapeworms include an anterior scolex and a series of segments (i.e., proglottids) that develop at the base of the scolex and extend distally as the worm grows (Fig. 280.1).

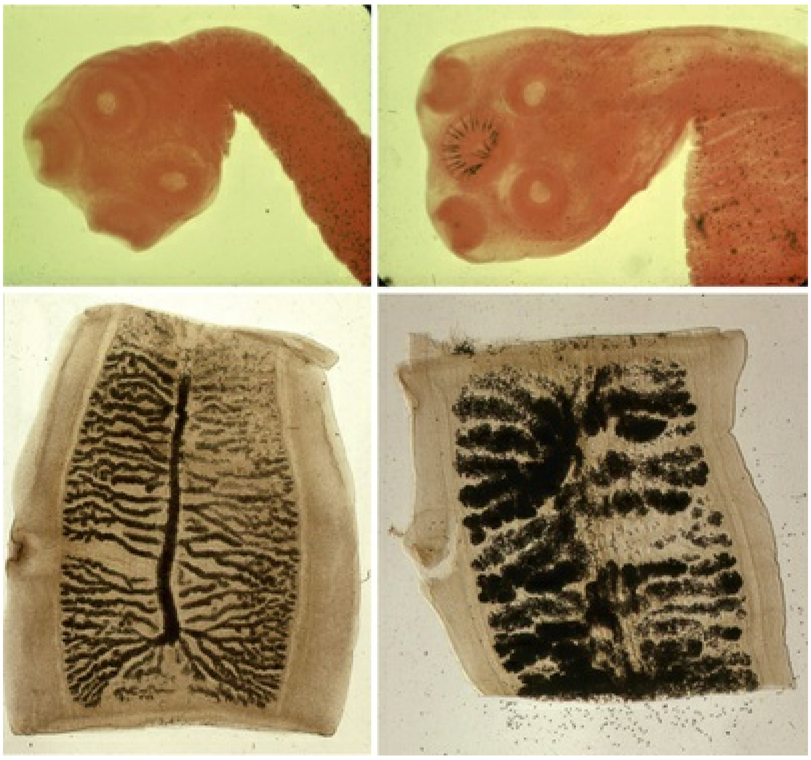

FIGURE 280.1 Scolices *(top)* and proglottids *(bottom)* from the tapeworms *Taenia saginata (left)* and *T. solium (right)*. The proglottids are excreted in the feces of infected people. (From U.S. Centers for Disease Control and Prevention. DPDx: Laboratory Identification of Parasitic Diseases of Public Health Concern. Last updated December 2016. https://www.cdc.gov/dpdx/.)

Like most cestodes, *Taenia saginata, Taenia asiatica,* and *Taenia solium* require an intermediate host to complete their life cycle and infect humans, who are the definitive hosts. In contrast, humans are accidental intermediate hosts for *Taenia multiceps* and *Taenia serialis,* the agents of coenurosis (see Chapter 282), and the tissue form of *T. solium* (i.e., cysticercosis).

Taeniasis

Key Points

Diagnosis and Management of Taeniasis

Parasitology

- Causative organisms include *Taenia saginata, Taenia solium,* and *Taenia asiatica.*

- Cattle and pigs are intermediate hosts; humans are the definitive hosts.
- Eggs passed in human stool must be ingested by intermediate hosts for completion of life cycle.

Epidemiology

- Infestation occurs after eating undercooked beef or pork containing cysticerci.
- Endemic in most areas around the world with poor sanitation and close contact between human feces and intermediate hosts

Diagnosis

- Recovery of eggs or proglottids in stool
- Species distinction cannot be made by evaluation of eggs.
- Injection of proglottids with India ink allows species differentiation by the number of uterine segments.
- Coproantigen detection by fecal enzyme immunoassay is available.

Treatment

- All children with intestinal tapeworm should be treated.
- Single-dose praziquantel (5–10 mg/kg) is the treatment of choice.
- Alternate agents include niclosamide (not available in the United States) and nitazoxanide.
- Albendazole is *not* recommended.

Epidemiology and Life Cycle

Taeniasis refers to intestinal infection with the human tapeworms *T. saginata, T. asiatica,* or *T. solium* (i.e., class Cestoidea in the phylum Platyhelminthes).[1] *T. saginata,* the beef tapeworm, is endemic in Africa, Eastern Europe, Latin America, the Middle East, and much of Asia. The prevalence in endemic areas where cattle raising is common can exceed 90%.[4] *T. solium,* the pork tapeworm, also has a worldwide geographic distribution, occurring in rural communities where raising pigs is a common practice.[5] Highly endemic areas include Latin America, sub-Saharan Africa, India, and Southeast Asia. The recently identified tapeworm *Taenia asiatica,* closely related to *T. saginata,* also is endemic in much of Asia.[6–9] Although the clinical presentation and adult worm morphology are similar to those of *T. saginata,* the intermediate host of *T. asiatica* is the pig. Although local transmission of *T. solium* has been described in the United States, most cases involve infection with the larval stages (i.e., cysticercosis) and not intestinal taeniasis.[10–14]

Infection with *T. saginata* is acquired by eating undercooked beef that contains cysticerci, which are larval forms of the parasite (Fig. 280.2). On entering the small intestine, the larvae excyst and attach to the mucosal surface using four suckers on the anterior scolex. Proglottids form at the base of the scolex and enlarge as they extend distally, a process referred to as *strobilization*. The segments pass through the large intestine and are excreted in the feces or actively exit the host by independent motility. Adult *T. saginata* tapeworms, which can grow to a length of 10 m, can survive within the intestine of an infected person for up to 25 years, shedding 6 to 10 proglottids daily, each of which contains up to 80,000 eggs.

The incubation period from the time of infection to the passage of *T. saginata* segments is approximately 10 weeks. After the intermediate bovine host ingests eggs or proglottids, emerging embryos invade the intestinal mucosa and disseminate through the bloodstream to subcutaneous tissues, where they form cysticerci. The life cycle resumes when the definitive human host ingests undercooked beef containing larval cysts. Unlike *T. solium,* ingested *T. saginata* eggs do not form cysticerci in humans.

Intestinal infection with *T. solium* and *T. asiatica* follows ingestion of undercooked pork containing cysticerci (see Fig. 280.2). After degradation of the cyst wall, the scolex attaches to the duodenal mucosa and develops into an adult in 6 to 8 weeks. Pigs, the intermediate host, ingest eggs contained in human waste. The eggs hatch in the stomach and release embryos that penetrate the pig's intestinal wall, and larval stages migrate through the bloodstream to muscle, subcutaneous tissues, or other organs. Humans complete the *T. solium* and *T. asiatica* life cycles by eating pork meat (*T. solium*) or viscera (*T. asiatica*) containing viable cysticerci.

Clinical Manifestations

Most people with *T. saginata* or *T. asiatica* infection are asymptomatic, but they become aware of tapeworm segments passing in feces.[4,15] The proglottids of *T. saginata* often are actively motile and people may notice them moving. Mild intermittent gastrointestinal symptoms such as nausea and epigastric pain have been reported, as have vomiting, diarrhea, and intestinal obstruction. Migration of proglottids down the thigh can be associated with pruritus.[4] Rarely, proglottid segments are vomited or migrate aberrantly, ultimately leading to appendicitis, cholecystitis, or colonic perforation.[16–18]

People harboring intestinal *T. solium* frequently are asymptomatic, becoming aware of tapeworm infection only on fecal passage of proglottids. The *T. solium* proglottid segments are less motile than those of *T. saginata,* and migration onto the perianal skin is commonly not noticed. Anal pruritus and urticaria have been described with heavy infections, which are sometimes associated with serum eosinophilia. Intestinal symptoms include nausea, abdominal pain, change in appetite, and diarrhea. However, frequent coinfection with other intestinal pathogens makes it difficult to ascribe these symptoms exclusively to taeniasis.

Laboratory Findings and Diagnostic Tests

A definitive diagnosis of intestinal taeniasis requires identification of proglottids or ova excreted from an infected person. To distinguish *T. saginata* or *T. asiatica* from *T. solium,* proglottids can be pressed gently between glass slides and injected with India ink through the lateral pore to visualize the uterine branches under light microscopy (see Fig. 280.1). *T. saginata* has 15 or more primary uterine branches on each side of the central core, and *T. solium* usually has less than 13 per side. Unlike *T. saginata* and *T. asiatica,* the scolex of *T. solium* possesses two rows of rostellar hooks, which it uses along with four suckers to attach to the mucosa of the small intestine.

Because patients infected with adult *T. solium* are at additional risk for cysticercosis due to autoinfection, attempts should be made to discriminate between *T. saginata* or *T. asiatica* and *T. solium* infection.[19,20] *Taenia* eggs, which rarely are present in fecal samples, cannot be distinguished based on morphology. Laboratory tests may reveal mild peripheral blood eosinophilia.

Coproantigen detection of *Taenia*-specific antigens by fecal enzyme immunoassay (EIA) is more sensitive than standard microscopy for detecting infection.[1,21–23] Immunodiagnostic and polymerase chain reaction (PCR)–based tests can detect *Taenia* antigens or DNA in feces and distinguish between the major species.[24–29] These assays have been used primarily in research settings, and their role in the routine diagnosis of tapeworm infections has not been established. Serodiagnostic testing for *Taenia* infection is used primarily for diagnosing cysticercosis, particularly involving the central nervous system (CNS). Serologic tests that are specific for the *T. solium* tapeworm carriers also have been developed but are not available widely.[3,30,31]

Treatment

Anthelmintic drug therapy is recommended for all children found to harbor an intestinal tapeworm. Praziquantel, administered orally in a single dose (5 to 10 mg/kg), is the drug of choice for taeniasis.[32,33] In children with *T. solium* infection, even modest doses of praziquantel occasionally can trigger the destruction of occult CNS cysts, particularly those in the brain parenchyma, perhaps leading to seizures.[34] Albendazole, although effective for treating cysticercosis, is not recommended routinely for the treatment of intestinal tapeworm infection.[35] Niclosamide (not marketed in the United States) and nitazoxanide can be used as alternatives.[36,37]

Effective treatment can be associated with passage of intact or disintegrating proglottids for days. However, purgatives (e.g., polyethylene glycol) can hasten the process and help identify passage of the scolex (as a test of cure). If the scolex is not identified, a second stool examination should be performed approximately 3 months after anthelmintic therapy, allowing time for regeneration of proglottids from the scolex. Because reinfection is common in endemic areas, repeated courses of therapy may be necessary for long-term control.

Special Considerations

Treatment of pregnant women with taeniasis can be complicated. The newborn infant could be exposed to infected stool if treatment is deferred until after delivery. Data on the safety of praziquantel in the setting of pregnancy are insufficient. One study chose to use niclosamide, which is not absorbed, as an alternative.[38]

Prevention and Control

Thorough cooking of meat is a key measure for the prevention of infection with *Taenia*. Transmission of taeniasis can be reduced by improving sanitation and husbandry practices, along with strict inspection of pork or beef before sale or consumption.[2,39,40] Unfortunately, in many resource-poor countries, these practices are not economically feasible. Public health measures such as sanitary disposal of human feces and restriction of cattle and pigs from land contaminated by human feces may also prevent transmission. Freezing meat at −20°C kills cysticerci but often is not practical in endemic areas.

No vaccine for human *T. saginata* infection exists. Protection of calves from challenge infection has been achieved after immunization with an oncospheral adhesion protein.[41]

Mass chemotherapy programs targeting communities where *T. solium* is highly endemic may reduce transmission from humans to pigs, thereby interrupting the natural life cycle of *T. solium*.[5,42] One intervention study demonstrated that the prevalence of human taeniasis was reduced from 4% to 1% within 10 months after treatment with niclosamide, and the seroprevalence of *T. solium* infection among pigs was reduced from 55% to 7%.[43] These strategies will likely have long-term benefit only if education succeeds in reducing the behaviors that encourage the proliferation and transmission of the parasite within high-risk communities. Vaccination of pigs using recombinant *T. solium* proteins has potential to limit the burden of disease in the porcine host, reducing the prevalence of taeniasis and cysticercosis among humans.[5,44–47]

Epidemiology

- Caused by the larval stage of *Taenia solium*
- Endemic in Latin America, Asia, and Africa
- Infestation occurs after ingestion of eggs or proglottids from a tapeworm carrier.
- Ingestion of pork is not a requirement for infection.
- Most common cause of seizures in developing countries

Clinical Features

- Symptoms depend on location of cysticerci

▪ Neurocysticercosis

▪ Parenchymal lesions characterized by seizures and headache

▪ Extraparenchymal lesions (e.g., intraventricular, basal cisterns) characterized by signs and symptoms of increased intracranial pressure

▪ Extracranial cysticercosis usually asymptomatic

Diagnosis

- Neuroimaging

▪ Computed tomography best displays calcifications.

▪ Magnetic resonance imaging best displays intraventricular and spinal lesions.

- Ophthalmologic examination to evaluate intraocular involvement
- Enzyme immunotransfer blot (EITB) available through the Centers for Disease Control and Prevention and commercially
- Symptom resolution with empiric therapy

Treatment

- Antiepileptic medications for patients with seizures
- Ventriculostomy or cerebrospinal fluid diversion for patients with increased intracranial pressure
- Corticosteroid (1 mg/kg/day of prednisone or 0.1 mg/kg/day of dexamethasone) in the setting of increased intracranial pressure, in patients receiving anthelmintic therapy, or for encephalitis
- Albendazole is the drug of choice, given as 15 mg/kg/day in 2 divided doses.
- Praziquantel is alternate therapy, administered as 3 doses (25 mg/kg/dose) given 2 hours apart (with cimetidine).
- Combination therapy can be considered in infections with a large parasitic load.
- Length of therapy depends on location of disease (e.g., up to 28 days for subarachnoid disease).
- Patients with calcified lesions do not require antiparasitic therapy.

Cysticercosis refers to infection of tissues or organs caused by larval stage (i.e., cysticercus) of *T. solium*. Neurocysticercosis (i.e., infection of the CNS) is recognized as a significant cause of neurologic disease in developing countries and is an emerging disease in the United States.[10,11,48–57]

Epidemiology and Pathogenesis

The availability of brain imaging studies, especially computed tomography (CT) scans, has led to an increased appreciation of the significance of neurocysticercosis as a common cause of neurologic disease. Neurocysticercosis is prevalent in many areas of the world, including Latin America, the Caribbean, sub-Saharan Africa, India, Southeast Asia, China, and Indonesia.[58] In endemic areas worldwide, neurocysticercosis is responsible for almost 30% of epilepsy cases.[59]

A community-based study in a highly endemic area of Peru showed that 40% of people with epilepsy had CT or serologic evidence of neurocysticercosis.[60] A meta-analysis of countries in Latin America estimated a neurocysticercosis prevalence of 32% among people with epilepsy.[61] Studies from Latin America also found that up to one half of patients with adult-onset seizures had evidence of neurocysticercosis on imaging studies.[62–66] Population-based surveys in Latin America and sub-Saharan Africa have documented CT abnormalities consistent with neurocysticercosis in up to 70% of people with seizures in rural communities.[49,67–69]

Among patients with focal seizures in India, CT scans demonstrated lesions consistent with neurocysticercosis in 40%, including viable cysts, typical calcifications, or single enhancing CT lesions.[70,71] Similar data were reported for children with seizures and for patients from northern India.[72] Although single-enhancing CT lesions in this group were frequently attributed to other causes, excisional biopsies demonstrated histopathologic evidence of cysticercosis in most. Neurocysticercosis also has become recognized as a major public health problem throughout Asia.[55,73–76]

In the United States, there are approximately 2000 hospitalizations for cysticercosis each year.[57] Cases primarily occur among immigrants from endemic areas. One review identified 75 cases of locally transmitted cysticercosis in the United States during the 1954–2005 period.[13] Neurocysticercosis also has been observed among long-term travelers to endemic areas.[77] The economic burden of neurocysticercosis cases in nonendemic areas can be substantial.[78]

Human cysticercosis follows ingestion of eggs excreted by a tapeworm-infected person, presumably by fecal-oral contamination. Neurocysticercosis is not acquired directly from eating pork, as illustrated by cases that have occurred in an Orthodox Jewish community in New York City, vegetarians in

India, and a case of CNS disease in an infant.[38,73,79] However, tapeworm carriers can infect themselves by fecal-oral contamination, and both stages of the parasite (i.e., cysticercus and adult tapeworm) can be found in a single person.

After ingestion, eggs hatch and release oncospheres that invade the circulatory system and disseminate to somatic tissues, where they mature into cysticerci. Cysticerci in skeletal and cardiac muscle, subcutaneous tissue, and lung usually spontaneously form granulomas, which calcify over time. However, most disease attributable to cysticercosis results from invasion of the CNS.

After tissue invasion, cysticerci reach their final size within a few weeks. Symptoms of neurologic disease, however, usually develop several years after infection.[10,12] Although the parasites secrete a variety of immunomodulatory compounds that can suppress the host's inflammatory response, cysticerci degenerate over time and trigger a host inflammatory response mediated by a variety of cytokines, which is associated with disruption of the blood-brain barrier.[80–89] Degradation of the parasite cyst occurs in stages. During the colloid stage, the cyst wall degenerates, with invasion by inflammatory cells. The cysticercus eventually fibroses, and the cavity collapses (i.e., granular-nodular stage). The granulomatous cyst can calcify (i.e., calcified stage). It may be possible to detect remnants of the cysticercus (e.g., hooklets) in the calcified lesion.

Clinical Manifestations

Seizures are the most frequent clinical finding of neurocysticercosis in all age groups.[90] Headaches, focal neurologic deficits, and signs of increased intracranial pressure are the next most common, but they tend to occur later in the clinical course and occur less frequently in children. The clinical features and outcome of neurocysticercosis in children are influenced by the number and location of the lesions (Fig. 280.3).[91–94]

Neurocysticercosis typically is separated into parenchymal and extraparenchymal disease based on whether there is involvement outside of brain tissue.[95–97] Extraparenchymal locations include the subarachnoid space, ventricles, spinal column, and the eye. A single patient can have parenchymal and extraparenchymal infections. Most children have seizures caused by a single enhancing parenchymal lesion; severe or fatal cases of neurocysticercosis often are associated with extraparenchymal disease.[94,98,99]

Patients with parenchymal lesions, particularly those with single enhancing lesions, have a favorable prognosis with medical therapy. In contrast, subarachnoid and ventricular cysts often cause increased intracranial pressure and hydrocephalus, which can be fatal without surgical intervention.

In addition to location, management of neurocysticercosis requires distinction between viable or degenerating parasites and residua of prior infection.[100–102] Viable cysticerci and degenerating parasites are demonstrated as cystic lesions on imaging studies, and they often respond to antiparasitic drugs. In contrast, imaging studies may reveal calcifications or chronic hydrocephalus caused by prior infection without parasites.

Parenchymal Neurocysticercosis.

Seizures are the main clinical manifestation of parenchymal neurocysticercosis.[91–93,103–105] Seizures usually are focal with secondary generalization.[49,51,67,103,106–110] An electroencephalogram (EEG) for patients with active disease can reveal focal abnormalities, particularly in those with a single inflamed lesion.[107,111] Most patients who have seizures due to neurocysticercosis have evidence of inflammation, including edema or contrast enhancement on neuroimaging studies. One study suggests that substance P may be a mediator of seizures.[112] In contrast, cysts without inflammatory changes are thought to cause few symptoms.[108,109] Most symptomatic infections are likely mediated by host inflammatory responses.

Seizures usually can be controlled during treatment with antiepileptic drugs and often resolve after normalization of imaging studies as the inflammation subsides.[113] Relapse, however, is common, particularly in patients who develop residual calcifications.[106]

One uncommon form of parenchymal disease is cysticercal encephalitis, which is characterized by large numbers of inflamed cysts with diffuse cerebral edema, increased intracranial pressure, seizures, and altered mental status. Cysticercal encephalitis occurs more commonly in children than adults, and it often is complicated by increased intracranial pressure and diffuse cerebral edema.[114]

Calcifications.

Calcifications typically are seen as parenchymal solid lesions measuring 2 to 10 mm in diameter, and they often are identified by CT.[102,115,116] In some patients, calcified lesions viewed by magnetic resonance imaging (MRI) are associated with enhancement and perilesional edema, and they are associated with chronic seizures.[117] Children with calcified lesions often have seizures but infrequently have focal abnormalities on the EEG.[118] One study found that some calcified cysts were associated with seizures, even in the absence of perilesional edema.[88]

Extraparenchymal Neurocysticercosis

Patients with ventricular neurocysticercosis most often come to attention with signs or symptoms of increased intracranial pressure, including nausea, vomiting, dizziness, vision changes, and altered mental status.[99,119–122] The onset of symptoms can be abrupt (due to acute obstruction), intermittent, or gradual. Approximately 10% to 20% of patients with symptomatic neurocysticercosis have evidence of ventricular cysts, which can cause hydrocephalus by obstructing the flow of cerebrospinal fluid (CSF).[123] Cysticerci can develop in any ventricle, and symptoms occur most often when cysts are still viable.[124,125] CT may show evidence of obstructive hydrocephalus or distortion of the involved ventricle, whereas the sensitivity of MRI may be greater for detecting intraventricular cysts.[125]

Subarachnoid neurocysticercosis cysts are located in the brain convexity gyri, large brain fissures, and basilar cisterns (i.e., racemose neurocysticercosis). Racemose neurocysticercosis has been associated with pituitary hormone deficiency, vision loss, sudden loss of consciousness associated with head position (i.e., Bruns syndrome), and dementia that improved after shunting.[126–129] Patients with cysticerci in the gyri of the cerebral convexities have imaging findings and a clinical presentation similar to those with active parenchymal disease. However, these cysts may be larger and not respond as well to chemotherapy.

Giant cysticerci, which can grow to several centimeters, can develop within cranial fissures.[130] These cysts can cause a significant mass effect and often are accompanied by cysticerci in the parenchyma or basilar cisterns. Cysticercosis of the basilar cisterns can be associated with communicating hydrocephalus or arachnoiditis, which can appear on neuroimaging studies as focal or diffuse meningeal enhancement or vasculitis.[102,131,132] Basilar cysticercosis carries a poor prognosis.

Isolated spinal disease occurs rarely in patients with neurocysticercosis. However, a study suggested that it is common (61%) among patients with basal subarachnoid disease.[10,94,99,133] Initially, spinal subarachnoid cysticerci are free floating and can move between levels. When the cysticerci degenerate, they eventually become fixed at one level. The accompanying inflammation can cause a mass effect with obstruction of CSF flow. Clinical manifestations include radicular paresthesias or pain, which can progress to myelopathy with bowel or bladder incontinence and paraparesis. Cysticerci rarely are intramedullary, causing cord compression from mass effect or accompanying inflammation.

The most common presentation of ocular cysticercosis is ptosis caused by involvement of extraocular muscles.[134–137] Involvement of the eye usually is subretinal but can be intravitreal or subconjunctival. Patients can have altered vision. Intraocular disease usually requires surgical removal of cysts.

Mixed Forms of Cysticercosis.

Clinical cases, especially those involving dissemination with large numbers of cysticerci, often include more than one of the previously described forms.[138–145] Pathogenesis and presentation can reflect each location. For example, patients with seizures usually have parenchymal cysticerci. However, some also have cysticerci in the basilar cisterns that can progress to hydrocephalus.

Associated Clinical Syndromes.

Cysticerci can be found in skin, muscle, soft tissues, and organs besides the brain, and they can be evident as calcifications.[138,139,141–143,145,146] Cysticerci of the subcutaneous tissues may appear as painless cystic lesions that are similar to sebaceous cysts.

Headaches are common among patients with neurocysticercosis and can occur with parenchymal, ventricular, or cisternal disease.[34,48,94,147,148] Headaches can be hemicranial or bilateral and are difficult to differentiate from migraine or tension headache. In some cases, headache is an initial symptom of raised intracranial pressure, whereas the association of parenchymal lesions with migraine-like headaches suggests vascular involvement. A study in Ecuador found an increased proportion of neurocysticercosis calcified lesions among patients with primary headache compared with patients with cerebrovascular disease, degenerative disorders, or head trauma.[149]

Diagnosis

The most common finding on brain imaging studies of patients with neurocysticercosis is one or more parenchymal cystic lesions.[10,12] Parenchymal cysticerci typically are 4 to 20 mm in diameter and localize to the cerebral cortex, whereas those that arise within fissures may be as large as 10 cm.[125,150] The fluid within viable cysticerci is initially isodense with CSF, and the scolex may be visible as a 1- to 3-mm nodule located on the cyst wall.[116,151] In contrast, inflamed cysts appear as ring-enhancing lesions, often with surrounding edema, and the cyst fluid can have increased density. Eventually, cysticerci can evolve into focal areas of enhancement or granulomas.

Calcifications within the parenchyma are a common radiographic finding and, in the absence of an alternative diagnosis (e.g., tuberculosis), should suggest neurocysticercosis. MRI may reveal edema and enhancement surrounding calcified lesions and a residual scolex.[124,152] Cysticerci within the ventricles may not be directly visualized by CT, although hydrocephalus can suggest their presence. Although CT is more sensitive than MRI for detecting calcifications, MRI provides superior resolution for cysticerci located in the ventricles and subarachnoid space.[124,125,152,153]

Issues with sensitivity and specificity have limited the usefulness of serologic assays in the diagnosis of cysticercosis.[31,62,154–161] The enzyme immunotransfer blot (EITB) is highly specific but has limited sensitivity in patients with single or calcified lesions.[156] The test is available through the US Centers for Disease Control and Prevention and commercially. The EITB test also can be performed on CSF, although the predictive value is superior with serum.[3,162–164] EIAs using recombinant proteins from the EITB test have been developed and have similar sensitivity and specificity, including limitations in detecting single or calcified lesions.[20,165–173]

Assays designed to detect circulating parasite antigens in serum, urine, or CSF have been developed. Although the presence of circulating *T. solium* antigens does not necessarily predict risk of clinical sequelae from infection, these tests can be used to monitor the response to therapy.[31,158,167,174–176] A PCR assay has been developed and has high sensitivity in the CSF, but it is not available widely.[177]

Criteria for the diagnosis of neurocysticercosis combining information from exposure history, clinical findings, neuroimaging studies, and serologic tests have been developed but not systematically evaluated.[178] A definite diagnosis requires the presence of one absolute criterion or two major criteria plus one minor and one epidemiologic criterion. Patients with one major criterion plus a history of exposure and one other minor criterion or those with three minor criteria plus exposure are considered probable cases.

The absolute diagnostic criteria require direct visualization of the parasite histologically in biopsy specimen of a lesion, funduscopic examination in ocular disease, or identification of the scolex within a cystic lesion by CT or MRI. The major diagnostic criteria include results of neuroimaging studies that strongly suggest neurocysticercosis (e.g., cystic lesions, ring-enhancing or nodular lesions, typical parenchymal calcifications). The lesions of neurocysticercosis typically are less than 20 mm in diameter and rarely cause a midline shift.[179] Other major criteria include a positive serum EITB result for anticysticercal antibodies and resolution of single or multiple cystic lesions spontaneously or after anticysticercal therapy.

Minor criteria include radiographic evidence of lesions that are consistent with but not pathognomonic for neurocysticercosis (e.g., basilar meningitis, hydrocephalus, filling defects in the spinal subarachnoid space in the absence of cysticerci). Additional minor criteria are symptoms suggesting neurocysticercosis (including seizures or hydrocephalus), a positive serologic result using a test other than the EITB, and the presence of cysticerci outside the nervous system (e.g., muscle calcifications, subcutaneous nodules). Risk factors for exposure and infection include residence or a prolonged stay in an endemic area and contact with a tapeworm carrier.

Other clinical and radiologic criteria have been proposed for cysticercal granulomas in patients who have seizures and single enhancing lesions.[179,180] The combination of a single, round, enhancing lesion that is more than 20 mm in diameter and does not produce a midline shift in patients with no signs of increased intracranial pressure, focal neurologic deficits, or evidence of systemic disease strongly suggests neurocysticercosis. These criteria, which were prospectively studied in 400 patients in India, had high sensitivity and specificity.

Treatment and Prognosis

The management and prognosis of neurocysticercosis requires consideration of several factors, including the stage of the disease and the number and location of cysticerci (Table 280.1).[10,94,106–108,181,182] Treatment guidelines for parenchymal neurocysticercosis have been developed.[183] Poor outcomes, including most fatalities, result from failure to provide effective therapy for complications, such as increased intracranial pressure or seizures. Symptomatic therapy is therefore a key element in the management of neurocysticercosis and should include antiepileptic medications for patients with seizures, corticosteroids for patients with diffuse cerebral edema, and surgical CSF-diverting procedures for patients with hydrocephalus.

TABLE 280.1

Treatment Guidelines for Neurocysticercosis

Target	Treatment
PARENCHYMAL NEUROCYSTICERCOSIS	
Vesicular Cysts	
Single	Albendazole 15 mg/kg/day (maximum dose: 800 mg) in 2 divided doses for 10–14 days with simultaneous use of corticosteroid *or* Praziquantel 75 mg/kg in 3 divided doses is an alternative to albendazole
Moderate infections	Albendazole 15 mg/kg/day in 2 divided doses for 10–14 days[a] with simultaneous use of corticosteroid
Heavy infections (≥100 cysts)	Albendazole 15 mg/kg/day in 2 divided doses for 10–14 days[a] with simultaneous high doses of corticosteroid
Degenerating (Colloidal) Cysts	
Single lesions	Albendazole 15 mg/kg/day in 2 divided doses for 10–14 days[a] with simultaneous use of corticosteroid or no antiparasitic treatment
Moderate infections	Albendazole 15 mg/kg/day in 2 divided doses for 10–14 days[a] with simultaneous use of corticosteroid
Heavy infections (encephalitis)	High doses of corticosteroid; antiparasitic treatment not indicated
Calcifications	
Single or multiple	No antiparasitic treatment
• Extraparenchymal neurocysticercosis	No antiparasitic treatment
• Subarachnoid neurocysticercosis	No antiparasitic treatment
Giant cyst (usually	Albendazole 15 mg/kg/day in 2 divided doses for ≥28 days[a] with high

in sylvian fissure)	doses of corticosteroid or surgical excision
Basal subarachnoid (racemose)	Albendazole 15 mg/kg/day in 2 divided doses for ≥28 days[a] with high doses of corticosteroid
Treatment failure	Albendazole 15 mg/kg/day in 2 divided doses for ≥28 days[a] *or* Albendazole 30 mg/kg/day for 15 days[a] *or* Praziquantel 50–100 mg/kg/day for 28 days *or* Albendazole 15 mg/kg/day[a] *plus* praziquantel 50 mg/kg/day for 15 days, monotherapy or dual therapy plus high doses of corticosteroid
Ventricular cysts	Endoscopic or surgical resection; alternatively, ventricular shunt plus albendazole 15 mg/kg/day in 2 divided doses for ≥28 days,[a] with high doses of corticosteroid or methotrexate
Hydrocephalus	No antiparasitic treatment; ventricular shunt
OTHER FORMS OF NEUROCYSTICERCOSIS	
Spinal cysts	Surgical resection, albendazole with corticosteroid may be used
Ocular cysts	Surgical resection

[a] Maximum albendazole dose is 800 mg/day (400 mg twice daily).

Antiseizure Medications.

Control of the seizures is the first priority and usually can be accomplished with established drugs such as phenytoin, phenobarbital, or carbamazepine.[109] Recurrent seizures usually are associated with subtherapeutic antiseizure drug levels, most often resulting from poor medication adherence.[109,113] Studies suggest many patients can be tapered off seizure medications after 1 or more years of symptom-free maintenance therapy, provided there is radiographic resolution of the lesion.[103,107–109,184,185] However, the rate of seizures after withdrawal of medications is as high as 40% in some populations.[123,132] Residual inflamed or calcified lesions are associated with continued seizure risk and may be an indication to continue antiepileptic drugs indefinitely.[186–188]

Corticosteroids.

The use of corticosteroids to control host inflammation is an essential component of therapy for certain forms of neurocysticercosis, including cysticercal encephalitis, subarachnoid neurocysticercosis, and spinal intramedullary cysticercosis. Although data on the optimal dose or duration of corticosteroid therapy are lacking, doses of 1 mg/kg/day of prednisone or 0.1 mg/kg/day of dexamethasone are used for severe disease. For patients with parenchymal lesions, coadministration of corticosteroids with antiparasitic drugs may reduce the potentially harmful host inflammatory reaction to parasite antigens. For patients with obstructive hydrocephalus caused by neurocysticercosis, corticosteroids in conjunction with antiparasitic drug treatment may decrease the rate of ventriculoperitoneal shunt failure.[97] However, a randomized, controlled trial found no difference in seizure control or resolution of solitary granuloma with corticosteroids, although fewer generalized seizures were observed.[189]

Antiparasitic Therapy.

The role of antiparasitic drugs in the treatment of neurocysticercosis has been controversial.[133,180,190] Early uncontrolled trials in Latin America suggested that antiparasitic drugs were associated with improved prognosis, but studies in the United States demonstrated that many single enhancing lesions resolved without antiparasitic therapy.[190] The first randomized, controlled trials of antiparasitic therapy for the management of neurocysticercosis were not published until the 1990s, and only recently has a consensus on optimal management begun to emerge.[97,98,106,109,191,192]

Praziquantel was the first antiparasitic drug reported to be effective in the treatment of neurocysticercosis.[193,194] Praziquantel is well absorbed after oral administration but has extensive first-pass metabolism that is enhanced by antiepileptic drugs and corticosteroids.[195,196] Coadministration of cimetidine increases blood levels of praziquantel, but effects of the increased drug levels have not been defined.[130,197–200] Adverse effects of therapy include worsening neurologic function, presumably due to the host inflammatory response to parasite antigens.[92,97]

Albendazole is a benzimidazole antiparasitic agent with broad-spectrum activity against nematodes and some cestodes.[92,97,201,202] The recommended dose of albendazole for the treatment of neurocysticercosis is 15 mg/kg/day in 2 divided doses.[92,93,105,109] Side effects are few and include mild gastrointestinal discomfort. Higher doses have been used for extraparenchymal infections.[92,97,203] Controlled trials of its use against parenchymal neurocysticercosis observed no difference in imaging resolution with treatment for 7 days compared with longer courses.[204–207] A 3-day course of albendazole was associated with more rapid resolution of single parenchymal lesions compared with placebo, although risk of seizure recurrence was not reduced.[208] A meta-analysis showed improved resolution of a solitary parenchymal granuloma and a reduction in seizure recurrence associated with albendazole treatment.[209]

Praziquantel has been used in combination with albendazole, and a pharmacokinetic study demonstrated increased levels of the active metabolite of albendazole in subjects receiving combination therapy.[210] No statistically significant improvement was observed among children with single parenchymal brain lesions treated with albendazole plus praziquantel compared with albendazole alone.[211] However, a randomized, controlled trial showed that 64% of patients receiving combination therapy had complete resolution of brain cysts, compared with only 37% of patients receiving standard doses of albendazole.[212]

The most common presentation of neurocysticercosis among children includes seizures and a single enhancing lesion seen on neuroimaging studies. Seizures usually respond to a single antiseizure medication. The lesions resolve spontaneously over months to years, but most studies show more rapid radiologic resolution with antiparasitic therapy.[97,98,106,109,180,213] Several studies have demonstrated seizure reduction with faster CT resolution of lesions as a benefit of corticosteroid therapy when used in conjunction with antiepileptic medications.[103,107,108,184]

Children with seizures and multiple cysticerci usually have at least one lesion that is inflamed, but other cysticerci often are viable. Recurrent seizures may reflect sequential degradation of cysticerci. A placebo-controlled trial demonstrated a small but statistically significant reduction in generalized seizures in patients treated with albendazole plus corticosteroids.[109] The difference increased after patients were tapered off antiseizure medications. Based on these results, most experts recommend that patients with multiple parenchymal cysticerci be treated with a course of antihelmintic (15 mg/kg/day of albendazole for 10–14 days) and a short course of corticosteroids concurrently. For patients with multiple cysticerci who have diffuse cerebral edema, antiparasitic therapy is contraindicated because the subsequent inflammatory response may worsen clinical sequelae. These patients should be treated with high-dose corticosteroids.[114] In most cases, the cysticerci resolve spontaneously with anti-inflammatory medications alone.

Antiparasitic drugs are not recommended for children with calcified neurocysticercosis because no viable parasites are likely to be present. However, because patients with calcified parenchymal lesions often experience recurrent seizures, they should be offered long-term antiepileptic therapy. Although calcified lesions can exhibit significant ring enhancement or edema, it remains to be determined whether treatment with corticosteroids is beneficial for controlling seizures in this circumstance.[115–118]

Surgical Therapy.

Cerebral edema may result in increased intracranial pressure, which usually can be managed with corticosteroids, or hydrocephalus, which often requires ventriculostomy or surgical CSF-diverting procedures.[181,214] Elective endoscopic removal of intraventricular cysticerci is the treatment of choice in the absence of ependymitis.[119,121,214–218] However, obstructive hydrocephalus caused by active ventricular neurocysticercosis is a medical emergency, and relieving hydrocephalus should be the first priority.[119,123,215,219–222]

For refractory hydrocephalus after endoscopic ventriculostomy or associated with inflamed basilar or racemose cysticercosis, placement of a ventriculoperitoneal shunt (compared with open craniotomy) is associated with a lower perioperative mortality rate.[223] One literature review suggested that anthelmintic therapy after cyst removal might be associated with a decreased need for shunting.[224] Patients who receive antiparasitic therapy along with shunting also require fewer shunt revisions than those who receive shunts alone.[223,225,226] Corticosteroids also may reduce the risk of shunt obstruction in the setting of neurocysticercosis.[97,123,130,131,227,228] In some patients, hydrocephalus develops after infection as a result of chronic inflammation and scarring (e.g., aqueductal stenosis).[97] These patients, who may require placement of a ventriculoperitoneal shunt to relieve chronic hydrocephalus, likely do not benefit from treatment with antiparasitic agents.

Other Anatomic Locations.

Subarachnoid cysticercosis, which can be complicated by a significant mass effect, communicating hydrocephalus, cerebral vasculitis, and basilar meningitis, carries a particularly poor prognosis.[119,130,131,227] These patients should receive prolonged courses of antihelmintics (e.g., 15 mg/kg/day of albendazole for at least 28 days) along with high doses of corticosteroids (1 mg/kg/day of prednisone or 0.1 mg/kg/day of dexamethasone). Even with this therapy, patients often develop recurrent symptoms, which may respond to repeated courses, prolonged duration, or higher doses of albendazole or to changing to or adding praziquantel.

Optimal therapy has not been defined for spinal neurocysticercosis. Intramedullary disease has usually been treated surgically because of the risk of paralysis from cord edema. Some cases of spinal cysts may respond to antiparasitic drugs.[229] Surgical removal of ocular cysts usually is recommended. No clearly defined role for anthelmintic therapy exists in this setting.

Special Considerations

Neurocysticercosis has been associated with several neurologic sequelae. Neurocognitive deficits, learning disabilities, depression, psychotic episodes, and hemorrhagic cerebrovascular disease have been described with cysticercosis.[230–236] However, acute alterations of mental status can reflect ongoing seizures or hydrocephalus. Altered mental status that does not resolve after a reasonable postictal period usually results from hydrocephalus.

Few reports in the literature have explored cysticercosis in the immunocompromised host. Because of the dependence on the host immune reaction for symptomatic disease, immunocompromised patients may be less likely to have symptomatic neurocysticercosis. In patients with concurrent human immunodeficiency virus (HIV) infection, the diagnosis of neurocysticercosis can be complex, especially for those living in endemic regions.[237] Empiric therapy with close observation for response may be warranted for these patients. Neurocysticercosis is more likely to be the cause of characteristic brain lesions and symptoms in people with higher $CD4^+$ lymphocyte counts.

Intrauterine or vertical transmission of infection has not been reported. However, pregnant women with neurocysticercosis can present a diagnostic dilemma because their symptoms can be mistaken for preeclampsia or eclampsia, and seizures can cause fetal hypoxia.[238–240] Albendazole is contraindicated in pregnancy, and antiepileptic medications may be relatively contraindicated. Treatment is often deferred until after delivery.

Prevention

Cysticercosis remains endemic in areas where pig farming is a common practice, and disease control has remained an elusive goal.[39,40,98,241] Educational efforts and mass drug administration to decrease human tapeworm carriers have shown the most potential but may not result in long-term reduction of the risk of neurocysticercosis.[42,239] Vaccination of pigs using recombinant *T. solium* antigens, when used in conjunction with antihelmintics, has the potential to reduce transmission to human populations in endemic areas.[45,47] Development of an effective human vaccine against cysticercosis may provide the best tool for eradication of the disease.

Echinococcus granulosus

Description of the Pathogen

Echinococcus granulosus, which causes cystic echinococcosis, is a cestode whose life cycle involves dogs and other canids as definitive hosts for the intestinal tapeworm and domestic and wild ungulates as intermediate hosts for the tissue-invading metacestode, which is the larval stage of the tapeworm (Fig. 281.1). The metacestode (i.e., echinococcal cyst) is a fluid-filled, spherical, unilocular cyst that consists of an inner germinal layer of cells supported by a characteristic acidophilic-staining, acellular, laminated membrane of variable thickness (Fig. 281.2).[1]

FIGURE 281.1 Life cycle of *Echinococcus granulosus*. The adult *E. granulosus* (3–6 mm long) resides in the small bowel of the definitive hosts (i.e., dogs or other canids). Gravid proglottids release eggs that are passed in the feces. After ingestion by a suitable intermediate host (i.e., sheep, goat, swine, cattle, horses, and camels under natural conditions), the egg hatches in the small bowel and releases an oncosphere that penetrates the intestinal wall and migrates through the circulatory system into various organs, especially the liver and lungs. In these organs, the oncosphere develops into a cyst that enlarges

gradually, producing protoscolices and daughter cysts that fill the cyst interior. The definitive host becomes infected by ingesting the cyst-containing organs of the infected intermediate host. After ingestion, the protoscolices evaginate, attach to the intestinal mucosa, and develop into adult stages in 32 to 80 days. The same life cycle occurs for *E. multilocularis* (1.2–3.7 mm long), but the definitive hosts are foxes and, to a lesser extent, dogs, cats, coyotes, and wolves; the intermediate host are small rodents; and larval growth (in the liver) remains in the proliferative stage indefinitely, resulting in invasion of the surrounding tissues. For *E. vogeli* (≤5.6 mm long), the definitive hosts are bush dogs and dogs; the intermediate hosts are rodents; and the larval stage (in the liver, lungs, and other organs) develops externally and internally, resulting in multiple vesicles. *E. oligarthrus* (≤2.9 mm long) has a life cycle that involves wild felids as definitive hosts and rodents as intermediate hosts. Humans become infected by ingesting eggs, with resulting release of oncospheres in the intestine and the development of cysts in various organs. (Data from the Centers for Disease Control and Prevention. DPDx—Laboratory Identification of Parasitic Diseases of Public Health Concern: Parasites—Echinococcosis. Last updated December 2012. https://www.cdc.gov/parasites/echinococcosis/.)

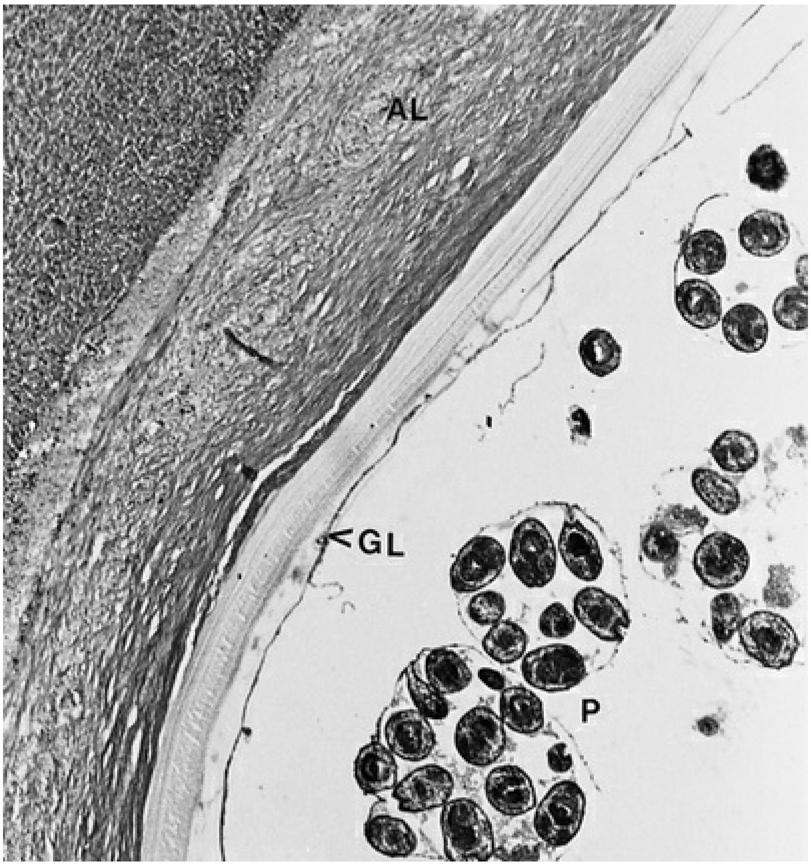

FIGURE 281.2 Metacestode (i.e., hydatid cyst) of *Echinococcus granulosus,* showing the protoscolices (P) in brood capsules, germinative layer (GL), laminated membrane, and adventitial layer (AL) or ectocyst (hematoxylin & eosin stain, bar = 100 μm).

Each cyst is surrounded by a host-produced layer of granulomatous adventitial reaction. Small vesicles (i.e., brood capsules) bud internally from the germinal layer and produce multiple protoscolices by asexual division. In humans, the slowly growing hydatid cysts can attain a volume of several liters and contain many thousands of protoscolices. With time, internal septations and daughter cysts can form, disrupting the unilocular pattern typical of the young echinococcal cysts.

Epidemiology

Geographically distinct strains of *E. granulosus* have different host affinities. Molecular studies using mitochondrial DNA sequences have identified 10 distinct genetic types (i.e., G1 to G10) of *E. granulosus.*[2,3] They include two sheep strains (G1 and G2), two bovid strains (G3 and G5), a horse strain (G4), the camelid strain

(G6), a pig strain (G7), and the cervid strain (G8). A ninth genotype (G9) has been described in swine in Poland and a 10th strain (G10) in reindeer in Eurasia.[2] The sheep strain (G1) is the form most commonly associated with human infections. The other strains appear to be distinct genetically, suggesting that the taxon *E. granulosus* is paraphyletic and may require taxonomic revision.[2,3] The cervid or northern sylvatic genotype (G8) is maintained in cycles involving wolves and dogs and moose and reindeer in northern North America and Eurasia. Human infection with this strain is characterized by predominant pulmonary localization, slower and more benign growth, and less frequent occurrence of clinical complications than reported for other forms.[2]

The distinct strains of *E. granulosus* may have important implications for public health. The shortened maturation time of the adult form of the parasite in the intestine of dogs suggests that the period for administering antiparasitic drugs to infected dogs should be shortened in areas where the G2, G5, and G6 strains occur.[4]

Certain human activities (e.g., widespread rural practice of feeding dogs the viscera of home-butchered sheep) facilitate transmission of the sheep strain and consequently raise the risk of human infection.[5] Dogs infected with *Echinococcus* tapeworms pass eggs in their feces, and humans become infected through fecal-oral contact. Eggs adhere to hairs around an infected dog's anus and are found on the muzzle and paws. Indirect transfer of eggs through contaminated water, uncooked food, or intermediary flies or other arthropods can result in infection of humans.

The greatest prevalence of cystic echinococcosis in human and animal hosts is found in countries of the temperate zones, including southern South America, the Mediterranean region, southern and central parts of the former Soviet Union, central Asia, China, Australia, and parts of Africa.[6–8] In the United States, most infections occur in immigrants from countries in which echinococcosis is highly endemic. Sporadic autochthonous transmission is recognized in Alaska, California, Utah, Arizona, and New Mexico.

Clinical Manifestations

After ingestion, *Echinococcus* eggs hatch and release embryos in the small intestine. Penetration through the mucosa leads to bloodstream distribution to the liver and other sites, where cyst development begins. Most primary infections in humans consist of a single cyst, but 20% to 40% of infected people have multiple cysts or multiple organ involvement.[9] The liver (>65%) and lungs (25%) are the most common sites for pastoral strain echinococcal cysts. The cyst occurs less frequently in the spleen, kidneys, heart, bone, and central nervous system.

Although infections can be acquired in childhood, most liver and lung cysts become symptomatic and are diagnosed in adult patients because of the slow growth. Only 10% to 20% of cases are diagnosed in patients younger than 16 years of age. Because cysts located in the brain or eye can cause clinical symptoms even when small, most cases of intracerebral echinococcosis are diagnosed in children. Clinical manifestations of cystic echinococcosis vary and are determined by the site, size, and condition of the cysts.[9] The rates of growth of cysts vary, ranging from 1 to 5 cm in diameter per year. A slow-growing echinococcal cyst often is well tolerated until it causes dysfunction because of its size.

Signs and symptoms of hepatic echinococcosis can include hepatic enlargement with or without a palpable mass in the right upper quadrant, right epigastric pain, nausea, and vomiting. If a cyst ruptures, the sudden release of its contents can precipitate allergic reactions ranging from mild to fatal anaphylaxis. In the lungs, ruptured cyst membranes can be evacuated entirely through the bronchi or can be retained and serve as a nidus for bacterial infection. Dissemination of protoscolices can result in multiple secondary sites of echinococcosis. Larval growth in bones is atypical; when it occurs, invasion of marrow cavities and spongiosa is common and causes extensive erosion of the bone.

Laboratory Findings and Diagnosis

The finding of a cyst-like mass in a person with a history of exposure to sheepdogs in areas in which *E. granulosus* is endemic supports the diagnosis of cystic echinococcosis. However, echinococcal cysts must be differentiated from benign cysts, cavitary tuberculosis, mycoses, abscesses, and benign or malignant neoplasms.

Noninvasive confirmation of the diagnosis usually can be accomplished with the combined use of radiologic imaging and immunodiagnostic techniques. Radiography permits detection of echinococcal cysts in lungs (Fig. 281.3); in other sites, calcification is necessary for radiographic visualization. Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography are useful for the diagnosis of deep-seated lesions in all organs and for determination of the extent and condition of the avascular fluid-filled cysts. Abdominal ultrasonography has emerged as the most widely used imaging technique for echinococcosis because of its widespread availability and usefulness for defining the number, site, dimensions, and vitality of cysts.[10–13]

referred for evaluation for malignancy. This Air Force family had been stationed in Spain and Germany for the preceding 7 years. Axial computed tomography of the chest (C) and abdomen (D) without contrast demonstrate large cysts in the lung and liver. Notice the daughter cyst in the liver (D). Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Antibody assays are useful to confirm presumptive radiologic diagnoses, although some patients with cystic echinococcosis do not demonstrate a detectable immune response.[14] Hepatic cysts are more likely to elicit an immune response than pulmonary cysts. Regardless of location, the sensitivity of serologic tests is related inversely to the degree of sequestration of the echinococcal antigens inside cysts. For example, healthy, intact cysts can elicit minimally detectable response, whereas previously ruptured or leaking cysts are associated with strong responses. Enzyme immunoassay and the indirect hemagglutination test are highly sensitive for initial screening of sera. Specific confirmation of reactivity can be obtained by demonstration of echinococcal antigens by immunodiffusion (arc 5) procedures or immunoblot assays (8/12-kd band).[15] Eosinophilia occurs in less than 25% of infected people.

The diagnosis of echinococcosis can be made through microscopic examination of cyst contents after cyst aspiration when other testing modalities fail to confirm the diagnosis but clinical suspicion remains high. Identification of hooklets is facilitated by acid-fast stains. Protoscolices sometimes can be demonstrated in sputum or bronchial washings in addition to cyst aspirates.

Treatment

The World Health Organization Informal Working Group on Echinococcosis (WHO-IWGE) recommends an image-based, stage-specific approach to the treatment of cystic echinococcus that includes options of surgery, chemotherapy, percutaneous treatment, or observation.[10,16] The size and stage of the cyst help to determine the treatment options.

Surgery

The aim of surgery is total removal of the cyst with avoidance of the adverse consequences of spilling the contents. Pericystectomy, or total removal of the cyst, is the usual procedure, but simple drainage, capitonnage, marsupialization, and resection of the involved organ can be performed, depending on the location and condition of the cyst.[17–21] The more radical the intervention, the higher the operative risk but the lower the likelihood of recurrence.

Surgery is the preferred treatment in several situations: large cysts with multiple daughter vesicles, single hepatic cysts that are situated superficially and may rupture spontaneously or from trauma; and infected cysts or cysts located in certain organs (i.e., brain, lung, or kidney). Surgery is contraindicated in patients who are pregnant, have preexisting medical conditions that put them at increased risk, or have multiple cysts that are difficult to access. Surgical risks include those associated with any surgical intervention and risks unique to echinococcosis (e.g., anaphylaxis, secondary recurrence). The operative mortality rate varies from 0.5% to 4% but rises with repeated interventions and when surgery is performed in inadequate facilities.

Chemotherapy

Experience with chemotherapy using benzimidazole compounds is extensive, and the medical approach can be recommended for many patients.[7] Approximately one third of patients treated with benzimidazole drugs are cured (i.e., complete and permanent disappearance of cysts) and even higher proportions (30% to 50%) have significant regression of cyst size and alleviation of symptoms.[22–25] However, 20% to 40% of people do not respond favorably. The small (<7 mm in diameter), isolated cysts surrounded by minimal adventitial reaction respond best, whereas complicated cysts, with multiple compartments or daughter cysts or with thick or calcified surrounding adventitial reactions, are relatively refractory to treatment.

Albendazole (10 to 15 mg/kg/day) and mebendazole (40 to 50 mg/kg/day) have demonstrated efficacy against cystic echinococcosis, but the results for albendazole have been superior, probably because of its pharmacokinetic profile, which comparatively favors intestinal absorption and penetration into the cyst.[16,26,27] Albendazole should be administered without interruption.[16] The optimal duration is uncertain; 1 to 3 months may be adequate, but up to 6 months may be required in some cases.

Administration of albendazole with fat-rich meals facilitates absorption and bioavailability. Adverse reactions (e.g., neutropenia, liver toxicity, alopecia) have occurred in a few patients but are reversible on cessation of treatment. Examinations for adverse reactions (i.e., aminotransferase levels and blood count) should be performed every 2 weeks during the first 3 months and then monthly for 1 year. Contraindications to chemotherapy include early pregnancy (albendazole may be acceptable under some circumstances), chronic hepatic diseases, and bone marrow depression.

Praziquantel has protoscolicidal activity, but its efficacy in clinical studies varies, and it is not recommended as primary therapy alone.[28,29] However, human case series and experimental animal studies suggest the combination of albendazole and praziquantel may be superior to the use of albendazole alone. Animal studies suggest that nitazoxanide is not effective against cystic echinococcosis.[30]

Percutaneous Treatments

Different modalities of percutaneous treatments have been developed.[16] One type, percutaneous aspiration, injection, and re-aspiration (PAIR), has been used extensively for the treatment of hydatid cysts. PAIR consists of percutaneous puncture using sonographic guidance, aspiration of substantial amounts of the liquid contents, injection of a protoscolicidal agent (e.g., 95% ethanol or hypertonic saline) for at least 15 minutes, and re-aspiration.[31–35]

PAIR is indicated for patients who cannot undergo surgery and for people who refuse surgery who have single or multiple cysts in the liver, abdominal cavity, spleen, kidney, and bones. PAIR is contraindicated for inaccessible or superficially located liver cysts and for inactive or calcified cystic lesions. To avoid sclerosing cholangitis, PAIR must not be performed in patients whose cysts have a biliary communication, which can be determined by testing the cyst fluid for bilirubin or by a surgical, endoscopic, or radiologic evaluation. Complications of PAIR include secondary infection of the cavity, acute allergic reactions, and recurrence; however, these have been rare. Application of PAIR to pulmonary cysts has been associated with frequent complications and is not recommended.

The physician using PAIR must be prepared to treat a life-threatening allergic reaction, which occurs in less than 1% of cases.[31,32] The possibility of secondary echinococcosis resulting from accidental spillage during this procedure can be minimized by concurrent treatment with benzimidazoles, and combined treatment may yield better results than chemotherapy or PAIR alone.[33,34] The recommended treatment course is 1 month of albendazole after the PAIR procedure.

Favorable results have been reported from more than 2000 PAIR interventions. A meta-analysis comparing the clinical outcomes for 769 patients with hepatic cystic echinococcosis treated with PAIR plus albendazole or mebendazole with 952 matched historical control subjects undergoing surgical intervention found greater clinical and parasitologic efficacy; lower rates of morbidity, mortality, and disease recurrence; and shorter hospital stays than with surgical treatment.[35]

Monitoring the Results of Treatment

The occult nature of the hydatid cyst confounds posttreatment evaluation. Objective response to treatment is best assessed with repeated evaluation of cyst size and consistency at 3-month intervals with CT, MRI, or ultrasound. The time to recurrence varies widely, and monitoring should be continued for at least 3 years. A change in the titer of serum antibody values is not reliable in itself to define the outcome of chemotherapy or PAIR.

Prevention

In areas endemic for cystic echinococcosis, personal preventive measures include careful hygiene, strict dietary regulation of pet dogs to preclude ingestion of sheep offal, and avoidance of dogs not so regulated. Periodic prophylactic treatment of pet dogs potentially exposed to *E. granulosus* sometimes is necessary.

Control measures include health education, regulation of livestock slaughtering, control of dogs, and periodic mass treatments of dogs with praziquantel (5 mg/kg) to reduce the prevalence of *E. granulosus* below levels favorable for continued transmission.[5,36] Development of effective vaccines for the metacestode stages of *E. granulosus* in livestock is a potential option for limiting transmission among animal hosts.[37]

Echinococcus multilocularis

Description of the Pathogen

Alveolar echinococcosis results from infection by the metacestode (larval) form of *Echinococcus multilocularis,* which therefore is also known as alveolar echinococcus. In rodents, the natural intermediate hosts, the larval mass proliferates rapidly by exogenous budding of germinative tissue and produces an alveolar-like pattern of microvesicles filled with protoscolices.[1] In humans, the larval mass resembles a malignancy in appearance and behavior, because it proliferates indefinitely by exogenous budding and invades surrounding tissues. Protoscolices are observed rarely in infections of humans.

Epidemiology

The *E. multilocularis* life cycle involves foxes and their rodent prey in ecosystems usually separate from humans.[38] However, there is ecologic overlap with humans because fox and coyote populations have encroached increasingly on suburban and urban areas of many regions, and domestic dogs or cats can become infected when they eat infected wild rodents.[36] Alveolar echinococcosis has been reported in parts of central Europe, much of Russia, the central Asian republics, western China, the northwestern portion of Canada, and western Alaska. Surveys in central Europe have extended the known distribution of *E. multilocularis* from four countries at the end of the 1980s to 11 countries in 1999, although the annual incidence of disease among humans remains low.[39] There is evidence that parasites are spreading from endemic to previously nonendemic areas in North America and Hokkaido

(North Island), Japan, principally due to movement or relocation of foxes.[39]

The prevalence and geographic spread in animal hosts appear to be rising in central North America. Hunters, trappers, and people who work with fox fur often are exposed to alveolar hydatid disease. Hyperendemic foci have been described in some Eskimo villages of the North American tundra and in western China because of the interaction between dogs and wild rodents that live as commensals in and around dwellings.[40,41] In central Europe, rodents inhabiting cultivated fields and gardens become infected by ingesting embryophores expelled by foxes and may be a source of infection for dogs and cats. One study demonstrated a higher risk of alveolar hydatidosis among people who owned dogs that killed game, dogs that roamed outdoors unattended, and farmers and people who owned cats.[42] In rural regions of central North America, the cycle involves foxes and rodents of the genera *Peromyscus* and *Microtus*.

Clinical Manifestations

The liver is the primary location of the metacestode of *E. multilocularis* in humans and in natural intermediate hosts. Local extension of the lesion and metastases to lungs and brain may follow.[9] In chronic alveolar echinococcosis infections, the lesion consists of a central necrotic cavity filled with a white amorphous material that is covered with a thin peripheral layer of dense fibrous tissue.[38] Focal areas of calcification exist, as does extensive infiltration by proliferating vesicles.

The initial symptoms of alveolar hydatid disease usually are vague. Mild upper quadrant and epigastric pain with hepatomegaly may progress to obstructive jaundice. The mortality rate for progressive, clinically manifest cases may be 50% to 75%. Death usually results from hepatic failure, invasion of contiguous structures, or less frequently, metastases to the brain.[38]

Laboratory Findings and Diagnosis

Alveolar echinococcosis typically becomes symptomatic in people of advanced age and closely mimics hepatic carcinoma or cirrhosis.

Plain radiographs show hepatomegaly and characteristic scattered areas of radiolucency outlined by calcific rings 2 to 4 mm in diameter. The usual CT image of *E. multilocularis* infection is that of indistinct solid tumors with central necrotic areas and perinecrotic, plaque-like calcifications (Fig. 281.4).[43] However, spontaneous death of the cyst has been reported in people with asymptomatic infection.[44]

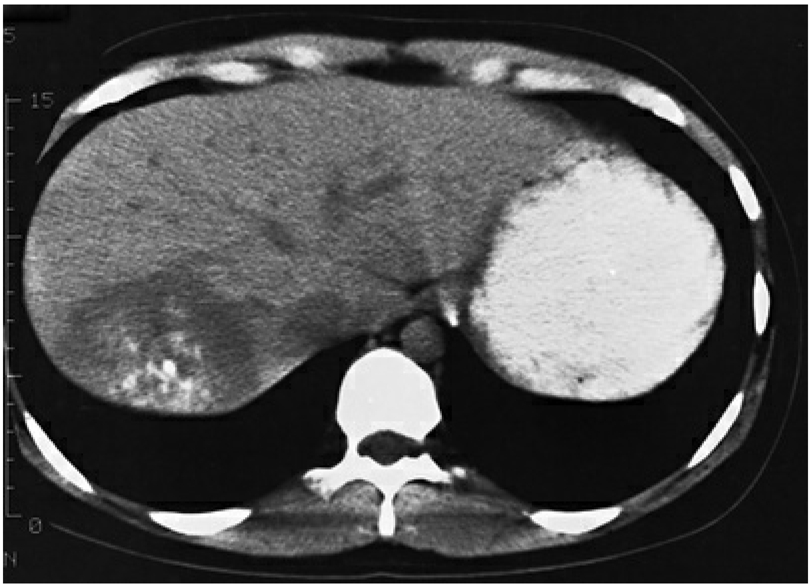

FIGURE 281.4 Abdominal computed tomography of a patient with an *Echinococcus multilocularis* lesion in the right lobe of the liver shows irregular, low-density zones that alternate with scattered areas of calcification. (Courtesy of Joseph F. Wilson, MD.)

Results of serologic tests usually are positive at high titers.; Purified *E. multilocularis* antigens are highly specific and permit serologic discrimination between infections with *E. multilocularis* and *E. granulosus*.[45] Needle biopsy of the liver can confirm the diagnosis if larval elements are demonstrated. Exploratory laparotomy often is performed for diagnosis and for determining the size and extent of invasion.

Treatment

Surgical resection of the entire larval mass, usually by excision of the entire affected lobe of the liver, is the preferred treatment; when involvement is extensive, wedge resections of the lesion can be attempted.[38] Because alveolar echinococcosis often is not diagnosed until disease is advanced, the lesion often is inoperable.

Long-term treatment with mebendazole (50 mg/kg/day) or albendazole (15 mg/kg/day) inhibits growth of larval *E. multilocularis*, reduces metastasis, and enhances the quality and length of survival; prolonged therapy eventually can be larvicidal in some patients.[16,46,47] Liver transplantation has been employed successfully in otherwise terminal cases.[48] In a Swiss study, therapy for nonresectable alveolar echinococcosis with mebendazole and albendazole resulted in an increased 10-year survival rate of approximately 80% (vs. 29% for untreated historical controls) and a 16- to 20-year survival rate of approximately 70% (vs. 0% for historical controls), respectively.[38]

Prevention

Because eliminating *E. multilocularis* from its wild animal hosts is impractical, contact with dogs and foxes in areas where the infection is endemic should be avoided. Preventing infection in humans depends on education to improve hygiene and sanitation.[5] Infection in dogs and cats prone to eating infected rodents can be prevented by monthly treatments with praziquantel.

Echinococcus vogeli

A polycystic form of echinococcosis is caused by *Echinococcus vogeli*, which therefore is also known as polycystic echinococcus, the life cycle of which involves the bush dog and possibly other wild canids; domestic dogs also are susceptible. Pacas, agoutis, and spiny rats are the principal intermediate hosts. *E. vogeli* is indigenous to the humid tropical forests in central and northern South America.[2,5] In endemic areas, hunting dogs are often fed the raw viscera of pacas, and the infected dogs then can expose humans. Polycystic echinococcosis has been recognized in humans in Panama, Ecuador, Colombia, Venezuela, and Brazil.[49,50]

The characteristics of polycystic echinococcosis are intermediate between those of the cystic and alveolar forms.[49] The relatively large cysts are filled with liquid and contain brood capsules with numerous protoscolices. The primary localization is in the liver, but cysts may spread to contiguous sites.

Techniques useful for the diagnosis of cystic or alveolar hydatid disease are also of value in polycystic hydatid disease. Because *E. vogeli* shares antigens with the other *Echinococcus* spp., most available immunodiagnostic tests do not permit species diagnosis. However, the hydatid cysts of *E. vogeli* are different from the cysts of other species in the dimensions of the hooks of the protoscolices.

Because lesions in polycystic echinococcosis are extensive, surgical resection is always difficult and usually incomplete.[49] A combination of surgery with albendazole therapy is most likely to be successful, although data are limited.[49] The principles of management for cystic and alveolar echinococcoses also apply to polycystic echinococcosis.

Key Points

Diagnosis and Management of Echinococcal Infection

Biology

- Lifecycle of *Echinococcus* species involves carnivores (e.g., canids) as definitive hosts and herbivores (i.e., domestic and wild ungulates) as intermediate hosts.
- The adult stage is small (2–12 mm long with 3 to 6 segments), and it localizes in the lower duodenum and jejunum of the final host.
- Larval or metacestode stages can develop in any organ (typically the liver), depending on the species of *Echinococcus* and species of intermediate host.
- Humans are incidental intermediate hosts.

Epidemiology

- Cystic echinococcosis is most prevalent in temperate zones in South America, the Mediterranean region, southern and central parts of the former Soviet Union, central Asia, China, Australia, and parts of Africa, where dogs often are fed hydatid-infected viscera from home-slaughtered sheep.

- Alveolar echinococcosis occurs in parts of central Europe, Russia, the republics of Central Asia, western China, the northwestern portion of Canada, and western Alaska. It appears to be spreading from endemic to previously nonendemic areas in North America and Hokkaido, Japan, principally due to the movement or relocation of foxes.

- Polycystic echinococcosis occurs in humid tropical forests of central and northern South America.

Clinical Features

- Most echinococcal cysts are asymptomatic.

- The liver is the most common site of the echinococcal cyst (>65%), followed by the lungs (25%). Cysts occur less frequently in the spleen, kidneys, heart, bone, and central nervous system.

- Clinical manifestations vary and are determined by the site, size, and condition of the cysts.

- Dissemination of protoscolices can result in multiple secondary sites of echinococcosis.

Diagnosis

- Chest roentgenography permits detection of echinococcal cysts in the lungs.

- CT, MRI, and ultrasonography are useful for detecting lesions in the liver and other organs.

- Serologic tests are useful for confirming a presumptive imaging diagnosis; however, a substantial proportion of patients with cystic echinococcosis may not develop a detectable antibody response

Treatment

- Surgery remains the treatment of choice for cysts that are large (>10 cm in diameter), secondarily infected, or located in certain organs (e.g., heart, brain)

- Continuous treatment with albendazole (10–15 mg/kg/day) or mebendazole (40–50 mg/kg/day) is effective depending on the classification of cyst

- Percutaneous puncture using ultrasound guidance, aspiration of substantial amounts of the liquid contents, injection of a protoscolicidal agent, and re-aspiration (PAIR) is an option for treatment of some classes of hydatid cysts in the liver and some other locations

- Liver transplantation has been employed successfully in otherwise terminal cases of alveolar echinococcosis

Taenia (Multiceps) multiceps and *Taenia serialis*

Coenurosis

Natalie J.M. Dailey Garnes, Jose A. Serpa, A. Clinton White Jr.

Coenurosis is human infection with larval forms of the animal tapeworms *Taenia (Multiceps) multiceps* or *Taenia serialis*.[1–8] The coenurus is a fluid-filled cyst that is a few millimeters to 2 cm or more in diameter. The wall is a thin, delicate membrane to which multiple invaginated scolices (i.e., protoscolices) are attached in rows or clusters. These zoonotic infections occur primarily in tropical and subtropical regions.

Epidemiology and Life Cycle

Fewer than 150 cases of coenurosis in humans have been reported, although potential exposure is common because of the widespread prevalence among dogs and other canids. Most cases of coenurosis occur in Africa, although the disease has also been reported in the United Kingdom, France, North America, the Middle East, and India.[7,9–11] Most cases from tropical Africa involve subcutaneous sites, whereas reported cases from South Africa and other temperate regions, including the United States, have a higher frequency of intracranial localization.[12–15] In North America, at least six cases of human autochthonous infection have been documented. Three cases involved the central nervous system (CNS), and the others involved intramuscular or subcutaneous localization.[12]

Adult *T. multiceps* and *T. serialis* tapeworms can be recovered from the small intestines of definitive canid hosts, including dogs, wolves, foxes, and coyotes.[16,17] An intermediate host ingests embryonated eggs or gravid proglottids in the environment. Oncospheres hatch within the intermediate host and circulate to the tissues, often the brain or spinal cord. The inner membrane (i.e., bladder) of the resulting cyst is composed of multiple protoscolices with additional small protoscolices or metacestodes contained within. Intermediate hosts for *T. multiceps* include various herbivores (e.g., sheep, goats, or horses), whereas *T. serialis* larvae most often are found in rabbits and squirrels. Human infestation is thought to occur by ingestion of food or water that has been contaminated with the feces of an infected animal, usually a dog.[18]

Clinical Manifestations

Human disease frequently involves the CNS, where it causes a cystic lesion.[3,7,8,13–15] Intracerebral cysts can cause headaches, personality changes, hemiparesis, weakness, nuchal rigidity, weight loss, increased intracranial pressure, or papilledema, and the disease can be confused with neurocysticercosis or echinococcosis.[19] Complications of coenurosis include meningitis, arteritis, arachnoiditis, ependymitis, and ocular involvement.[14] Intraparenchymal lesions of the spinal cord have been reported rarely.[19] Subcutaneous and intramuscular cysts are reported most commonly in Africa and involve the intercostal area, axillae, or anterior abdominal wall.[3,16,17] Allergic symptoms, such as recurrent urticaria, fever, and night sweats, also have been reported.

Laboratory Findings and Diagnosis

A presumptive diagnosis of coenurosis most often is based on results of imaging studies, including magnetic resonance imaging (MRI), computed tomography (CT), and ultrasound.[5,7] The pressure of the cerebrospinal fluid (CSF) often is elevated. Analysis of the CSF may show lymphocytic pleocytosis and reduced glucose and elevated protein concentrations.

A definitive diagnosis requires surgical excision and histopathologic identification of the parasite.[7,20] Fine-needle aspiration of a cyst also may yield a diagnosis.[14,21] Coenurus larvae are easily distinguished morphologically from cysticerci and hydatid cysts on the basis of the numbers and characteristics of their protoscolices (Fig. 282.1). When protoscolices are absent or not identifiable, coenurid cysts can be distinguished from echinococcal cysts because of their lack of the characteristic acellular, laminated membrane that is typical of the latter. However, racemose (acephalic) cysticerci often cannot be differentiated from coenuri because the thin cyst membranes are similar.[2]

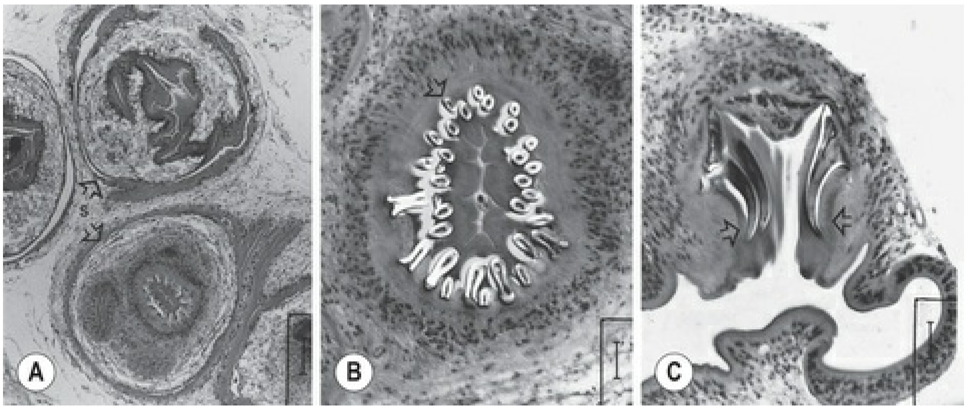

FIGURE 282.1 (A) Photomicrograph of section of the coenurus. Notice the two typically formed protoscolices (S, *arrows*) in the late stages of development, with suckers and a fully formed rostellum evident (hematoxylin & eosin [H&E] stain, bar = 100 μm). (B) Photomicrograph of transverse section through the rostellum of a fully developed protoscolex. Notice the typical distribution of approximately 30 rostellar hooks *(arrow)* in two rows (H&E stain, bar = 25 μm). (C) Photomicrograph of longitudinal section through the rostellum. Notice the structure of the blades in the typically formed rostellar hooks *(arrows)*; the guards and handles have not developed (H&E stain, bar = 25 μm). (From Huss BT, Miller MA, Corwin RM, et al. Fatal cerebral coenurosis in a

cat. J Am Vet Med Assoc 1994;205:69.)

Polymerase chain reaction–based restriction fragment length polymorphism (PCR-RFLP) has been used experimentally to differentiate various species of taeniid cestodes, including *T. multiceps* and *T. serialis*.[12,22] This technique may prove useful for diagnostic and epidemiologic purposes because there is no reliable serologic test for coenurosis.

Treatment

Surgical intervention has been the mainstay of therapy. Excision is indicated in most symptomatic cases involving the CNS, and it may be successful in people with small intraparenchymal or single intraventricular cysts.

Praziquantel and albendazole have been used to treat coenurosis,[7,14] but efficacy has not been evaluated in controlled trials. Because treatment with praziquantel can result in inflammation of previously unidentified intraocular cysts, a dilated ophthalmologic examination is recommended before initiation of therapy.[19]

Prevention

When infection of humans is traced to domesticated dogs and ungulates, strict management of animal slaughter, periodic treatment of dogs, and health education can be used to limit transmission. Transmission from wild animal hosts is more difficult to prevent. Measures are limited to careful avoidance of potentially infected carnivores and adequate hygiene. A recombinant protein vaccine against *T. multiceps* has shown significant protection against infection when administered to sheep in an endemic area.[23,24]

Key Points

Diagnosis and Management of Coenurosis

Parasitology

- Caused by the larval stage of *Taenia multiceps* or *Taenia serialis*

Epidemiology

- Most cases in Africa; rarely reported in United States
- Associated with consumption of contaminated food and water
- Definitive hosts are canids, including dogs and wolves.

Diagnosis

- Often diagnosed by neuroimaging
- Definitive diagnosis made by surgical excision and pathologic evaluation

Treatment

- Surgical excision is most helpful.
- Successful therapy with praziquantel or albendazole is reported, but there are no randomized trials to support this practice.
- Patients should undergo dilated ophthalmologic examination before praziquantel administration.

Intestinal Trematodes

LeAnne M. Fox

More than 70 species of zoonotic, hermaphroditic intestinal flukes can parasitize the human intestine.[1–5] Most human infections are asymptomatic, but heavy infections are more likely to result in clinical disease.

Adult flukes are flat and leaf-shaped, ranging in length from a few millimeters to several centimeters. They attach to the intestinal mucosa by means of oral and ventral suckers and release eggs having a characteristic operculum at one end of the shell. When deposited into fresh water, the operculum opens to release a miracidium, the free-swimming, ciliated larval stage of the parasitic fluke that finds and penetrates an appropriate snail host, in which further replication occurs. The infected snail eventually releases thousands of cercariae into water that encyst (as metacercariae) on aquatic plants or on or in a second intermediate host (i.e., fish, mollusks, crustaceans, and amphibians). When ingested by humans and other definitive hosts, the metacercariae develop into adult flukes.

Some of the more common intestinal trematodes are *Fasciolopsis buski, Heterophyes heterophyes, Metagonimus yokogawai,* and the echinostomes (Table 283.1). However, *Metorchis conjunctus, Nanophyetus salmincola, Gastrodiscoides hominis, Centrocestus formosanus, Haplorchis* species, and others infect humans.[1–6] All intestinal trematodes can be treated easily with oral praziquantel.

Fasciolopsiasis

Description

Fasciolopsiasis is a small bowel infection caused by the largest of the intestinal trematodes, *F. buski,* which can measure up to 7.5 × 2.5 cm. Eggs passed in feces hatch, and miracidia infect planorbid snails. Cercariae that emerge from the snails encyst on freshwater vegetation (i.e., bamboo shoots, water chestnuts, water caltrop, water lilies, hyacinths, and morning glory) and remain infectious for up to 1 year.[7] After ingestion, the metacercariae develop into mature flukes in 3 months.[1–3]

Epidemiology

F. buski is found throughout the Far East and Southeast Asia, including southern China, Taiwan, Bangladesh, India, Indonesia, Thailand, Malaysia, Sumatra, Cambodia, Philippines, Vietnam, Laos, and Myanmar.[1–3] Pigs are important reservoirs of the infection, although dogs and rabbits also can be infected.[1–3] Children, who tend to eat plants with encysted cercariae, have the highest prevalence rates.

Pathology and Symptoms

Most infections are asymptomatic. Ulcers or abscesses develop at the site of attachment to the intestinal mucosa in the duodenum and jejunum, and those infected may complain of epigastric pain indistinguishable from peptic ulcer disease. Eosinophilia is common, and anemia can be seen in severe cases. Children can come to medical attention because of systemic allergic manifestations attributed to absorption of parasite metabolites.[1] In cases of heavy infections, an edematous condition resulting from protein-losing enteropathy has been reported. Large numbers of flukes in the intestine may cause ileus or intermittent obstruction.

Diagnosis

The diagnosis is made by identification of large (135 × 80 μm), operculated eggs in stool. Eggs can be confused with those of *Fasciola hepatica, Fasciola gigantica,* and the echinostomes, which are similar morphologically. Stool concentration techniques, which allow examination of 1 g or more of stool, enhance detection of light infections.

Treatment

The drug of choice for children and adults is praziquantel, administered as 75 mg/kg/day divided into 3 doses.[6] Confusion of fasciolopsiasis eggs with eggs from fascioliasis (i.e., liver fluke infection) results in ineffective treatment for the latter, which is resistant to praziquantel.

Prevention

In endemic areas, freshwater plants should be cooked before being eaten. Better control of the infection can be achieved by prohibition of night soil use as fertilizer and proper disposal of human and pig excreta.[1–3]

Heterophyiasis and Metagonimiasis

Description

Infection by the intestinal flukes *H. heterophyes* and *M. yokogawai* occur in different geographic areas, but they are clinically and pathologically similar. The importance of these flukes is being increasingly recognized.[8]

The adults are small (1.4 × 0.6 mm), and they inhabit the small intestine and release eggs that pass in the feces. Miracidia from eggs infect snails, which release cercariae that encyst (as metacercariae) on the scales and occasionally in muscles of freshwater fish. The fins, tail, and gills are most heavily infected. The life cycle is completed when the definitive hosts (including humans) become infected by ingesting raw or undercooked fish. Incompletely salted or pickled fish also are infectious.[9] The metacercariae are released from the cysts and develop into adults in about 7 days.[1–3]

Epidemiology

Human heterophyiasis is common in Egypt, Iran, Tunisia, Turkey, and Sudan.[1–3] Besides humans, the parasite occurs in dogs, cats, foxes, birds, and a number of other fish-eating mammals. Metagonimiasis occurs in the Far East and Siberia (i.e., Taiwan, China, the Philippines, Korea, Indonesia, Japan, and Russia).[1–3] Adult *M. yokogawai* reside in humans, dogs, cats, pigs, and some other fish-eating birds such as pelicans. Humans are infected from eating undercooked freshwater fish, including salmon and trout. Infection rates can reach 65% among children in places where these fish traditionally are eaten raw.

Pathology and Symptoms

Most people are asymptomatic, but when large numbers of flukes are present, the clinical picture is one of intermittent diarrhea with mucus, abdominal tenderness, and discomfort. Occasionally, the flukes penetrate the intestinal wall and form granulomas in the peritoneal cavity. Rarely, eggs can gain access to the lymphatics and then to the bloodstream, embolizing to cause granulomatous lesions in the brain, heart, lungs, spleen, and liver, where they can incite serious disease.[3]

Diagnosis

Eosinophilia is common. The diagnosis is based on the finding of characteristic small (30 × 15 µm), operculated eggs in feces or tissues. Stool concentration techniques, which allow examination of 1 g or more of stool, enhance detection of light infections.

Heterophyes and *Metagonimus* eggs are indistinguishable from eggs of the liver flukes *Clonorchis* and *Opisthorchis.*[1,9] Because all of these flukes are sensitive to praziquantel treatment, an error in diagnosis does not jeopardize successful treatment.

Treatment

Treatment consists of praziquantel, administered as 75 mg/kg/day divided into 3 doses.[6]

Prevention

Fish should be carefully cleaned and scaled and then cooked well. Health education should discourage the ingestion of raw, undercooked, or improperly pickled or salted fish.

Echinostome Infections

Description

The name *echinostome* refers to the characteristic spines surrounding the oral and ventral suckers of the adult flukes.[1–3] At least 15 species of echinostomes have been observed in humans.[3] The life cycle is similar to that of other intestinal trematodes. Besides humans, reservoir hosts are dogs, cats, rats, and birds.[10] Infection is acquired in humans from ingestion of metacercariae on raw or undercooked fish, mollusks, crustaceans, and amphibians.

Epidemiology

Human echinostome infections are found in Korea, Indonesia, the Philippines, Malaysia, Thailand, China, and Taiwan.[1–3]

Pathology and Symptoms

Symptoms related to inflammation at the attachment site of adult flukes include abdominal pain, diarrhea, and anorexia. Symptom severity is related to infection intensity.

Diagnosis

The diagnosis is made by identification of large (135 × 80 µm), operculated eggs in stool that are difficult to distinguish from the eggs of *F. hepatica, F. gigantica,* and *F. buski.* Stool concentration techniques, which allow examination of 1 g or more of stool, enhance detection of light infections.

Treatment

Praziquantel (25 mg/kg in a single dose) is curative. Albendazole (400 mg twice daily for 3 days) also is effective. Confusion of echinostome eggs with eggs from fascioliasis (i.e., liver fluke infection) results in ineffective treatment for the latter, which is resistant to praziquantel.

Prevention

In endemic areas, raw or insufficiently cooked snails, fish, frogs, tadpoles, mollusks, and aquatic animals should not be eaten.[11]

Liver and lung trematodes are hermaphroditic, zoonotic flukes that use snails as intermediate hosts (Table 284.1). Snails are infected by eggs in feces passed into the environment by humans and other mammals. The snails release cercariae that encyst in second intermediate hosts (i.e., fish, crustaceans, and amphibians) or on water plants. When encysted cercariae are ingested, humans and other definitive hosts become infected.

[a] Principal sources of infection include uncooked plants, water, or poorly cooked, salted, and pickled fish or crustaceans.

Clonorchis, *Opisthorchis*, and *Fasciola* species invade the biliary tree, whereas *Paragonimus* species most often invade the lung. *Clonorchis* and *Opisthorchis* are among the most common causes of biliary fluke infection, affecting an estimated 35 million people and 12 million people, respectively. An estimated 17 million people are infected with *Fasciola* species.[1–3]

Clonorchiasis and Opisthorchiasis

Description of the Pathogens

The adult *Clonorchis* worms are flat, elongated flukes, measuring up to 25 mm long and 5 mm wide. Adult *Opisthorchis* worms are smaller and measure up to 12 mm long and 3 mm wide. The flukes inhabit the biliary tract, where they produce eggs that are passed into feces. Snails ingest these eggs, become infected, and release thousands of cercariae into water. The cercariae encyst (as metacercariae) in tissues of susceptible fish and shrimp.

More than 100 species of freshwater fish and several species of freshwater shrimp are susceptible to infection. When infected raw or undercooked fish or shrimp are ingested, the larvae excyst in the duodenum and migrate through the ampulla of Vater to the bile ducts, where they mature into adults in approximately 4 weeks.[3–6]

The adult flukes can live as long as 30 years.

Epidemiology

Infections occur where it is customary to eat raw fish dishes. Men are most affected in some areas, but in parts of China, children catch and eat small fish and become heavily infected. *Clonorchis sinensis* infects an estimated 15 million people in China. The infection also occurs in Korea, Taiwan, Vietnam, and Japan.[1,2] Infections in Hong Kong probably are a result of imported fish. Pigs, cats, and dogs are reservoir hosts of *C. sinensis*.

Opisthorchis viverrini is endemic in Thailand, Cambodia, Vietnam, and Laos and has reservoirs in dogs, whereas *Opisthorchis felineus* is found particularly in Eastern Europe and Siberia and is most common in cats. An estimated 10 million people are infected with *O. viverrini,* and approximately 1.6 million are infected with *O. felineus*.[2,3] Outbreaks of *O. felineus* infection associated with ingestion of freshwater lake fish have been reported from Italy.[7]

Clinical Manifestations

Adult flukes can be found in bile ducts, the pancreatic duct, and gallbladder. Infection produces inflammatory and hyperplastic changes in the epithelium of bile ducts, with sludging of bile. Eggs and flukes can serve as a nidus for formation of stones. The gallbladder and liver commonly become enlarged, but liver function usually is preserved, and portal cirrhosis can occur in chronic infection.[1,8,9]

Most infections are asymptomatic or produce only epigastric discomfort and are discovered only incidentally on routine screening examination of stool. In moderate to severe infection, an acute syndrome of fever, loss of appetite, diarrhea, right upper quadrant pain, hepatomegaly, and eosinophilia can occur approximately 2 to 4 weeks after ingestion of infected fish or shrimp.[1,2] In endemic areas, the prevalence of infection increases with age and often plateaus in late adolescence or early adulthood, but symptoms may not occur until the third decade or later.[2] Complications include pyogenic cholangitis, obstructive jaundice, gallstones, pancreatitis, and cholangiocarcinoma.

Laboratory Findings and Diagnostic Tests

In chronic disease, serum hepatic transaminase levels usually remain normal, but direct and indirect bilirubin and alkaline phosphatase values may be elevated. Definitive diagnosis is made through identification of eggs in stool or in duodenal aspirates or identification of adult worms during surgery. To improve the chance of finding eggs, multiple examinations using a stool concentration technique may be necessary. *Clonorchis* and *Opisthorchis* eggs are small (~30 × 15 μm) and yellowish brown, with an operculum that rests on a distinctive rim, and they often are difficult to distinguish from each other.[5,6]

Serologic tests have been developed but usually are not readily available outside of endemic areas and may not always have optimal specificity.[1] When available, a combination of serologic testing and morphologic examination improves diagnostic sensitivity. Molecular detection methods for fecal samples are also under investigation.[3,10]

Cholangiography, ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) demonstrates hepatobiliary dilation, sludging, stones, and neoplasia. Adult flukes sometimes can be seen as shadows or filling defects in endoscopic retrograde cholangiography.[11] M-mode ultrasonography can show mobile worms in gallbladder ducts.[12]

Treatment

Treatment consists of praziquantel in a dose of 25 mg/kg given three times per day for 2 consecutive days (>90% cure rate).[13,14] The safety of praziquantel has not been established in children younger than 4 years of age, but many children younger than 4 years of age have been treated without reported adverse effects in mass prevention campaigns and in studies of schistosomiasis.[15]

Praziquantel is a US Food and Drug Administration (FDA) pregnancy category B medication. Animal studies have revealed no evidence of harm to the fetus, but there are no adequate studies in pregnant women. Side effects include malaise, headache, dizziness, abdominal discomfort, elevated temperature, and urticaria; these effects usually are mild, time limited, and do not require intervention.

Alternative therapy for *C. sinensis* infection is albendazole (10 mg/kg/day for 7 days). The safety of albendazole in children younger than 6 years of age is not certain, but the World Health Organization (WHO) guidelines for mass prevention campaigns use albendazole in children 1 year of age or older. Many children younger than 6 years of age have been treated in these campaigns, albeit at a reduced dose.[15] Tribendimidine trials have shown good efficacy in the treatment of *C. sinensis* and *O. viverrini* infections in Asia, although further investigation is needed.[16,17]

After successful treatment, eggs usually disappear from the stool within a week. Biliary changes usually are reversible in children, but damage from longstanding infection in adults is slow to resolve and may not resolve. Secondary pyogenic cholangitis is treated with appropriate antimicrobial therapy.

Special Considerations

An increased incidence of cholangiocarcinoma is associated with *Clonorchis sinensis* and *Opisthorchis viverrini* infections.[1,18,19] Pathologically, tumors are primarily adenocarcinomas originating from the epithelial lining of bile ducts.[18] *Opisthorchis*-endemic areas may have a 15-fold excessive risk of cholangiocarcinoma with heavy infection. *N*-nitrosamines in food may be an important cofactor in inducing the neoplasia.[19]

Prevention

Thoroughly cooking freshwater fish and shrimp to 63°C (145°F) prevents infection; freezing to −20°C (−4°F) for 7 days also prevents infection. Travelers should be advised to avoid eating raw freshwater fish and shrimp. The practice of using night soil to enrich fish ponds should be discouraged. Repeated mass treatment of populations with praziquantel every 6 to 12 months has been used for clonorchiasis control in China.[20]

Fascioliasis

Description of the Pathogens

Fascioliasis is a widespread disease of sheep, goats, and cattle caused by the liver fluke *Fasciola hepatica* and less commonly caused by *Fasciola gigantica.* Humans become infected by eating uncooked, infested aquatic vegetation (e.g., watercress).

These large (*F. hepatica*, up to 30 × 13 mm; *F. gigantica*, up to 75 mm), flat, leaf-shaped adult flukes inhabit the bile ducts, gallbladder, and occasionally ectopic sites.[2,21] Eggs passed in feces hatch into miracidia and penetrate snails. Cercariae emerge after 4 to 7 weeks and encyst (appearing as small white dots) on watercress or other aquatic plants. Herbivorous mammals (e.g., cattle, sheep, goats, buffalo, llamas, camels, pigs, deer, rabbits) become infected by grazing or indirectly by drinking the surrounding water contaminated with metacercariae.[19,21]

The metacercariae release larvae that are more invasive in their migration than *Clonorchis* and *Opisthorchis* larvae. *Fasciola* larvae penetrate the duodenal wall, invade the peritoneal cavity, and then invade the liver, where they cause eosinophilic tracks 1 to 4 mm in diameter and focal necrotic abscesses as they move through the parenchyma. When they reach the bile ducts, they mature into adults and begin to produce eggs 3 to 4 months after infection.[19,21] Adult flukes live up to 10 years.

Epidemiology

Human infection occurs worldwide and is most common among rural people who tend sheep and eat uncooked water vegetables. Estimates of infection range from 2.4 to 17 million people in Asia, Africa, Europe (including western Europe and the United Kingdom), and the Americas.[2] Especially high infection prevalence rates have been recorded in Bolivia, Ecuador, and Peru, and concerns of potentially increasing prevalence rates in parts of Egypt have prompted clinical studies.[19,22] Cases have been reported from the United States, but most recognized cases are imported.[23,24] Animals also suffer considerable morbidity from these infections, known as *liver rot*.[2]

Clinical Manifestations

The tissue-invasive nature of *Fasciola* larvae can result in an acute or subacute clinical syndrome lasting for many weeks. Illness is characterized by fever, eosinophilia, and epigastric or right upper quadrant abdominal pain, rarely accompanied with ascites or right pleural effusion. Serum hepatic transaminase levels, direct and indirect bilirubin, and alkaline phosphatase values can be elevated.

When acute symptoms occur, they usually begin within 6 to 12 weeks after ingestion of metacercariae. After the adult parasites enter the bile ducts, systemic symptoms and laboratory abnormalities abate, and the infection can become asymptomatic. Patients with heavy infections can have clinical manifestations similar to those of clonorchiasis or opisthorchiasis, with jaundice, cholangitis, or gallstones, but cholangiocarcinoma has not been associated with fascioliasis.[1,2,19]

Complications of fascioliasis include acute hemorrhage from the biliary tract that can manifest as hematemesis or melena or aberrant larval migration that can result in ectopic abscesses or nodules in the skin, intestine, lung, heart, and brain. An unusual form of fascioliasis can occur after ingestion of raw *Fasciola*-infected liver, when flukes surviving mastication attach to the posterior pharynx, causing hemorrhagic nasopharyngitis and dysphagia.

Laboratory Findings and Diagnostic Tests

Acute hepatitis accompanied by eosinophilia and a history of travel or ingestion of watercress suggests fascioliasis. Assays for antibody, which are available at some specialty laboratories, can be helpful in making the diagnosis of acute fascioliasis.[24] Antibody tests are helpful when acute symptoms occur because eggs become detectable in the stool only 1 to 2 months after symptoms develop. Antibody test sensitivities of more than 90% have been reported, but specificities may not be optimal due to cross-reaction with other helminths.[25] Research is ongoing to develop better antigens to improve sensitivity and specificity of serologic tests and to develop sensitive and specific coproantigen tests.[2,26]

Diagnosis of chronic infection is made through identification in stool of large (130–150 μm long × 60–90 μm wide) eggs with poorly defined opercula.[21] The eggs are confused easily with eggs of the intestinal trematode *Fasciolopsis buski*. Examination of multiple stool specimens using concentration techniques should be undertaken because egg output usually is low. Chronic hepatobiliary tract involvement can be assessed using ultrasonography, cholangiography, CT, or MRI. Ulrasound results can be negative in cases of acute disease. High-definition CT or MRI can be useful in demonstrating the tracks of migrating larvae in the liver or filling defects in the gallbladder.[19,27] Spurious fascioliasis occurs when *Fasciola* eggs are found in uninfected people who recently have ingested cooked or uncooked liver from infected animals.

Treatment

Praziquantel is not an effective treatment for fascioliasis. Triclabendazole is effective in a single dose of 10 mg/kg for 1 or 2 days, but the human preparation is in short supply and is not FDA approved for use in the United States.[13,14] Triclabendazole is available through the Centers for Disease Control and Prevention (CDC) Drug Service (phone: 404-639-3670) under an investigational protocol. If available, a second course of triclabendazole treatment can be given if parasitologic cure is not achieved after the first course.[28]

Triclabendazole has not been assigned a pregnancy category by the FDA. Data on the use of triclabendazole in pregnant women are limited, although the available evidence suggests a low risk of congenital anomalies. In large-scale interventions for which the WHO has determined that the benefit of treatment outweighs the risk, triclabendazole is used in pregnant women in clinical settings where medical staff can monitor for complications. Because it is not known whether triclabendazole is excreted in breast milk, it should be used with caution in breastfeeding women.

The safety of triclabendazole in children has not been established. In mass treatment programs for which the WHO has determined that the benefit of treatment outweighs the risk, triclabendazole is used in school-age children; use in children younger than 4 years of age is limited to settings where medical staff can monitor for complications.[15]

Bithionol is an alternative therapeutic agent that is no longer used commonly and not generally available in the United States, although it may be available through a compounding pharmacy. It requires a long treatment course of 30 to 50 mg/kg orally given on alternate days for 10 to 15 doses, and it often causes considerable gastrointestinal tract side effects.

A 7-day course of nitazoxanide produced fascioliasis cure rates of 60% for adults and 40% for children in randomized trials (i.e., dosage of 100 mg twice per day for children 1–3 years old, 200 mg twice per day for those 4–11 years old, and 500 mg twice per day for those 12 years or older), some higher cure rates have been reported in case series.[22,29,30] Artesunate has shown some success in initial symptom control, it but showed a poorer response than triclabendazole at 3 months.[31] In an exploratory phase II trial, artemether showed little effect against fascioliasis.[32] A short course of corticosteroids may be indicated for acute disease.

Prevention

Travelers should be advised not to eat uncooked watercress or other aquatic plants. Washing these vegetables in water, vinegar, or lemon juice does not remove the metacercariae. Aquatic vegetable cultivation should be protected from fecal contamination. Where economically feasible, mollusks can be eliminated by drainage of land or use of chemical molluscicides. Oropharyngeal fascioliasis can be prevented by eating well-cooked liver.

Paragonimiasis

Description of the Pathogens

Human paragonimiasis is acquired through ingestion of *Paragonimus* spp. in raw or undercooked freshwater crabs or crayfish. After ingestion, metacercariae excyst in the small intestine and release larvae that penetrate the duodenal wall and enter the peritoneal cavity. Larvae migrate for approximately 1 week and then penetrate the diaphragm, enter the pleural cavity, and migrate directly through lung tissue to reach the bronchi. There they form cystic cavities and develop into adult worms within approximately 2 months.[1,19]

The adult parasites are reddish brown and ovoid, measuring approximately 7.5 to 12 mm long and 4 to 6 mm wide.[19,33] Adult worms induce an inflammatory response in the lungs, generating a fibrous cyst that contains a purulent, bloody effusion. Eggs released by the flukes are passed into the environment by expectoration, or they may be swallowed and passed with feces. When deposited in fresh water, eggs hatch to release miracidia, which then invade specific snail hosts. Thousands of cercariae later are released from an infected snail, which encyst as metacercariae in the gills, muscles, legs, and viscera of freshwater crustaceans (i.e., crabs or crayfish).

Epidemiology

Eight to 10 species of *Paragonimus* cause most human infections. The most important is *P. westermani,* which occurs primarily in Asia (i.e., China, the Philippines, Japan, Vietnam, South Korea, Taiwan, and Thailand).[19,34,35] *P. africanus* is an important human pathogen in Africa, as is *P. mexicanus* in Central and South America.

Various mammals may be infected, including domestic cats and dogs.[1,19,33] Although rare, human paragonimiasis from *P. kellicotti* has been acquired in the United States, with multiple cases reported from the Midwest.[35,36] Cases have been associated with ingestion of uncooked crawfish during float trips in Missouri.[36,37] Specialty dishes and seasonings in which shellfish are consumed raw or prepared in vinegar, brine, or wine without cooking play a key role in the transmission of *Paragonimus*. Raw crabs or crayfish have also been used in traditional medicine practices in Korea and Japan.[1,19] Eating raw wild boar, which can serve as a paratenic host, has led to infection in Japan.[1,19]

Clinical Manifestations

An acute syndrome characterized by cough, abdominal pain, malaise, low-grade fever, and eosinophilia can occur 2 to 15 days after infection and resolve without treatment. Light infections can be asymptomatic. The clinical picture of chronic paragonimiasis resembles chronic bronchitis or tuberculosis. Patients can have cough productive of tenacious coffee-colored or blood-tinged sputum, dyspnea, pleuritic chest pain, or secondary pyogenic infection.

The spectrum of abnormalities on chest radiographs includes lobar infiltrate, coin lesion, cavity, pneumothorax, calcified nodule, hilar enlargement, pleural thickening, and effusion (Fig. 284.1).[16,37,38] In a North American paragonimiasis case series, the most common chest CT findings were pleural effusion and internal mammary and cardiophrenic lymphadenopathy.[39] Pericardial involvement and omental inflammation were also common, and many nodules had a linear track to the surface that might have corresponded to the worm's burrow tunnel.[39] Ring-shaped opacities of contiguous cavities giving the characteristic appearance of a bunch of grapes strongly suggest pulmonary paragonimiasis.

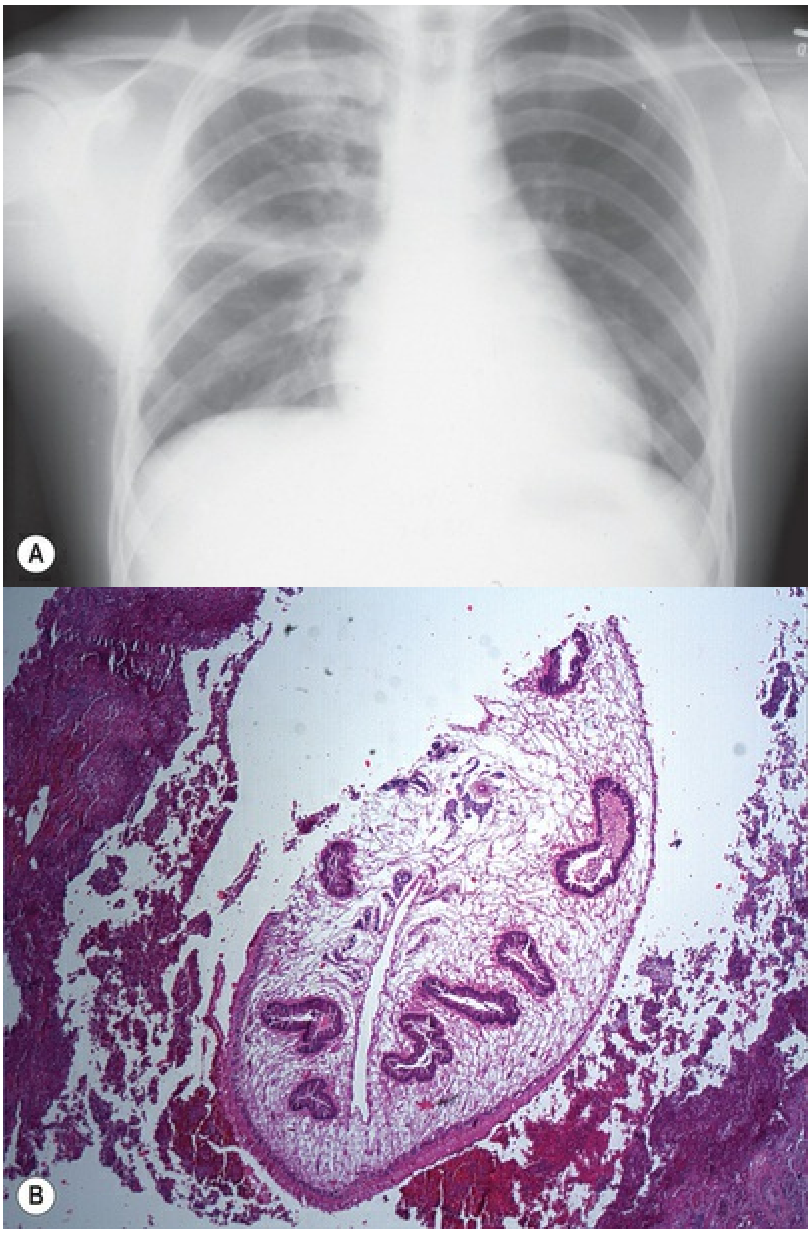

FIGURE 284.1 A 17-year-old boy who had recently emigrated from Laos came to medical attention

because of hemoptysis. He had a 1-year history (in Laos) of cough, chest pain, and dyspnea on exertion. The purified protein derivative test result was negative, and the peripheral blood eosinophil count was 3000 cells/mm^3. (A) Chest radiograph showed right upper lobe complex cystic disease. (B) Resected lung revealed multiple cavitary granulomatous lesions with necrosis and a predominant eosinophilic inflammatory response. *Paragonimus westermani* was also seen (×20) in the gastrointestinal tract. (Courtesy of D.V. Schidlow, J. Pascasio, and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Central nervous system (CNS) involvement occurs in up to 25% of hospitalized patients and can manifest as meningitis and space-occupying lesions. Symptoms include headaches, seizures, motor or sensory deficits, and visual disturbances. Skull radiographs can show clusters of calcified cysts resembling soap bubbles. CT and MRI also may show “grape bunch” findings of aggregated ring-enhancing lesions with surrounding edema, characteristically occurring in the temporal and occipital lobes.

Ectopic lesions from aberrant migration of flukes can involve any organ, including the abdominal viscera, heart, and mediastinum. The most clinically recognizable ectopic lesions arise from cerebral paragonimiasis, which in highly endemic countries more commonly affects children and adults younger than 30 years of age.[19,35] Patients can have eosinophilic meningoencephalitis, seizures, or signs of space-occupying lesions. Many patients with CNS disease also have pulmonary infection. *P. skrjabini* often produces skin nodules, subcutaneous abscesses, or a type of creeping eruption known as *trematode larva migrans*.

Laboratory Findings and Diagnostic Tests

Peripheral blood eosinophilia is common and can be intense, especially during the early larval migration stages. Definitive diagnosis is usually made by visualization of *Paragonimus* eggs in sputum, bronchial, or stool samples. Eggs are yellowish brown, 80 to 120 μm long and 45 to 70 μm wide, and thick shelled with an obvious operculum. Their presence in sputum or stool is diagnostic.[33] Because acid-fast staining destroys *Paragonimus* eggs, the diagnosis cannot be made on sputa prepared with acid-fast stain for tuberculosis testing. Stool examination or gastric aspirates (i.e., looking for swallowed eggs) can be useful for diagnosis. Multiple stools on different days should be examined using a stool concentration technique.

A specific and sensitive immunoblot test based on *P. westermani* antigens is available through the CDC (phone: 404-718-4100).[40] A sensitive and specific Western blot test based on the *P. kellicotti* antigen has been developed and should be helpful in the diagnosis and evaluation of *Paragonimus* infections from North America.[41] Serologic tests can be useful for early infections (i.e., before maturation of flukes) or for ectopic infections in which eggs are not passed in the stool.

Treatment

Praziquantel (25 mg/kg given three times per day for 2 consecutive days) usually produces cure rates higher than 90%.[13,14] For cerebral disease, a short course of corticosteroids should be given with the praziquantel to reduce the inflammatory response around dying flukes.

Triclabendazole (10 mg/kg for 1 or 2 days) is an alternative. Bithionol (30–50 mg/kg on alternate days for 10 to 15 doses) is a less commonly used alternative drug. See the earlier discussion on clonorchiasis and opisthorchiasis for additional information about praziquantel and the section on fascioliasis for additional information about triclabendazole and bithionol.

Prevention

Metacercariae are killed if crabs and crayfish are cooked for at least 5 minutes at 55°C (131°F). Travelers should be advised to avoid traditional meals containing raw or undercooked freshwater crustaceans.

Key Points

Epidemiology, Clinical Features, Diagnosis, and Treatment of *Clonorchis, Opisthorchis, Fasciola*, and *Paragonimus* Species

Epidemiology

- *Clonorchis* spp. and *Opisthorchis* spp.
  - *C. sinensis* and *O. viverrini* are most prevalent in Asia.
  - *O. felineus* is prevalent in Europe, especially Eastern Europe.
  - Infection results from ingesting of undercooked freshwater fish or shrimp.
  - *C. sinensis* and *O. viverrini* infections are associated with cholangiocarcinoma.
- *Fasciola* spp.
  - Occurs throughout most of the world
  - Infection results from ingesting undercooked water vegetables, particularly watercress.
- *Paragonimus* spp.
  - Occurs throughout the world
  - Most important species infecting humans is *P. westermani* in eastern Asia.
  - *P. kellicotti* causes infection in North America.
  - Infection results from ingesting undercooked freshwater crabs or crayfish.

Clinical Features

- Clonorchiasis and Opisthorchiasis
  - Most chronic infections are asymptomatic.
  - Acute syndrome of fever, loss of appetite, diarrhea, right upper quadrant pain, and hepatomegaly can occur about 2–4 weeks after infection.
  - Complications include cholangitis, cholecystitis, gallstones, obstructive jaundice, and cholangiocarcinoma.
- Fascioliasis
  - Acute clinical syndrome lasting for weeks can include fever, epigastric or right upper quadrant pain, eosinophilia, and in rare cases, ascites or right pleural effusion.
  - In heavy infections, cholangitis, gallstones, and jaundice can occur.
- Paragonimiasis
  - Acute syndrome is characterized by cough, abdominal pain, malaise, low-grade fever, and eosinophilia 2 to 15 days after infection.
  - Chronic paragonimiasis resembles chronic bronchitis or tuberculosis with coffee-colored or blood-tinged sputum, dyspnea, and pleuritic chest pain.

- Central nervous system (CNS) involvement can occur.

Diagnosis

- Clonorchiasis and Opisthorchiasis

- Identify eggs in stool or duodenal aspirates or adult worms during surgery

- Serologic tests may be available in endemic areas but can be nonspecific.

- If available, molecular detection methods for fecal samples can be helpful.

- Imaging using ultrasonography, CT, and MRI are useful adjunct diagnostic tools.

- Fascioliasis

- Identify eggs in stool or duodenal aspirates in the chronic phase of infection

- Serologic tests can support the diagnosis before eggs appear in the stool or when low levels of eggs are shed.

- Imaging studies using ultrasonography, CT, and MRI are useful adjunct diagnostic tools.

- Paragonimiasis

- Visualize *Paragonimus* eggs in sputum, bronchial, or stool samples

- Sensitive and specific immunoblot tests use *P. westermani* and *P. kellicotti* antigens.

- Chest radiograph can show lobar infiltrate, cavity, coin lesion, hilar enlargement, pleural thickening, and effusion.

- In CNS disease, CT or MRI can show aggregated ring-enhancing lesions with edema.

- Peripheral blood eosinophilia is common, especially during early phases of infection.

- Migratory skin lesions that resemble cutaneous larval migrans can occur, especially with *P. skrjabini* infection.

Treatment

- *Clonorchiasis* spp. and *Opisthorchiasis* spp.

- Praziquantel: 25 mg/kg three times per day for 2 consecutive days (for children ≥4 years old and adults)

- Albendazole: 10 mg/kg for 7 days (children ≥6 years old and adults)

- *Fascioliasis* spp.

- Triclabendazole: 10 mg/kg for 1 or 2 days (adults)

- Bithionol: 30–50 mg/kg (given on alternate days) for 10 to 15 doses (adults; not available in the United States)
- Nitazoxanide: 7-day course at 100 mg twice per day (children 1–3 years old); 200 mg twice per day (4–11 years old); or 500 mg twice per day (≥12 years)

- *Paragonimiasis* spp.

- Praziquantel: 25 mg/kg 3 times per day for 2 consecutive days (children ≥4 years old and adults)
- Triclabendazole: 10 mg/kg for 1 or 2 days (adults)
- Bithionol: 30–50 mg/kg (given on alternate days) for 10 to 15 doses (adults; not available in the United States)
- For CNS disease, corticosteroids may be required to reduce the inflammatory response.

Blood Trematodes

Schistosomiasis

Susan P. Montgomery, Frank O. Richards Jr.

Schistosomiasis (i.e., bilharzia or snail fever) is a parasitic infection caused by trematodes that reside in the circulatory system. More than 230 million people worldwide suffer from schistosomiasis, which causes a range of clinical disease from overt clinical manifestations to subtle hindrance of day-to-day activities. Infected children can have impaired growth and development. Infection occurs from exposure to freshwater into which snails, the intermediate host of the parasite, have shed cercariae that can penetrate skin.

The three main species of schistosomes that parasitize humans are *Schistosoma mansoni, S. japonicum,* and *S. haematobium.* Gastrointestinal and hepatic disease is caused by infection with *S. mansoni* or *S. japonicum*, and urogenital tract disease results from *S. haematobium* infection. Other schistosome species less commonly infect humans, including *S. intercalatum*, which is found in Cameroon and the Democratic Republic of Congo, and *S. mekongi,* which is found primarily in the Mekong River basin. Both species cause gastrointestinal disease.[1]

Biology

The complicated life cycle alternates between parasitic forms in the snail intermediate host and human definitive host and the free-living forms in water, the cercariae and the miracidia (Fig. 285.1). The cercariae are released from infected snails and penetrate intact human skin, where they transform into schistosomula that travel through the venous system to the lungs. From the lungs, schistosomula enter the arterial system; reach the liver, where they attain sexual maturity in 4 to 6 weeks; and then as adult worms descend against the blood flow of the portal venous system to the venules of the intestine (*S. mansoni* or *S. japonicum*) or bladder (*S. haematobium*).

FIGURE 285.1 Life cycle of *Schistosoma* and occurrence of schistosomiasis.

Unlike other trematodes, schistosomes are not hermaphroditic. Males and females mate, and the females begin to deposit eggs. Eggs must pass through tissue to reach the lumen of the intestine or bladder and then on to the environment in feces or urine. About one half of the eggs are retained in intestinal or vesicular tissues, where they cause granulomatous inflammation and fibrosis. In the case of the intestinal *Schistosoma* species, eggs also can be swept by the portal blood system back to the liver, where they can cause similar pathologic changes.

Eggs that exit the body and reach freshwater hatch and release miracidia that infect certain genera of snails. *S. mansoni* infects snails of the *Biomphalaria* species, *S. haematobium* infects *Bulinus* species, and *S. japonicum* infects *Oncomelania* snails. In the receptive snail, a single miracidium forms sporocysts from which thousands of cercariae are released into the water over the lifetime of the infected snail, typically a period of 6 to 12 months.[1]

Epidemiology

Schistosomiasis is transmitted in 76 countries in tropical and subtropical areas, but 85% of infected people reside in Africa, where *S. mansoni* and *S. haematobium* occur and often are coendemic.[1–3] *S. mansoni* was transplanted, likely with the slave trade, to South America (especially Brazil, Venezuela, and Suriname) and several islands in the Caribbean (Antigua, Dominican Republic, Guadeloupe, Martinique, Montserrat, Puerto Rico, and Saint Lucia).[3] *S. haematobium* also occurs in a few countries of the Middle East, and a recent focus of transmission has been reported in Corsica, France.[4] *S. japonicum* is endemic in China, the Philippines, and Indonesia.[1–3]

People most heavily infected are responsible for most environmental contamination with parasite eggs. Cross-sectional studies of *S. haematobium* and *S. mansoni* show that the highest prevalence of infection occurs among school-aged children 10 to 14 years of age and that rates decrease in adulthood. Infants have been infected from being bathed in irrigation canals or in lake or river water.[5,6] Males are infected more often than females, and certain daily activities and occupations (e.g., fishing, doing laundry, washing cars) are important risk factors. Wide variations in community prevalence patterns and disease focality point to complex interactions with the environment and practices of human waste disposal, water contact, and acquired immunity. Hydraulic dams and irrigation projects often increase snail habitats and the risk of transmission.

Expatriates, missionaries, diplomats, Peace Corps volunteers, and other long-term residents of endemic areas are at particular risk. However, tourists also can become infected, particularly those who take part in adventure or ecotourism.[7]

Pathogenesis

The host immune response to schistosome egg antigens results in the major clinical and pathologic manifestations of schistosomiasis.[1] Cercarial penetration of skin can give rise to a local hypersensitivity reaction and papular dermatitis, usually within 72 hours of exposure.[7] This reaction typically is milder than the allergic rash associated with skin penetration of animal schistosome cercariae. Adult worm maturation and sudden exposure to antigens with the onset of egg laying by young female worms can result in an acute illness resembling serum sickness, which is more often reported in travelers than lifelong residents of endemic regions.[1,7,8]

Chronic organ damage and dysfunction are related to the number of eggs in tissues, which is related to the number of egg-laying female worms. People with a heavy worm load and the heaviest tissue egg load are at greatest risk of disease. The worm burden in humans grows only through repeated exposure to water containing cercariae. Some evidence suggests that humans acquire partial immunity to reinfection, but the mechanism of a protective immune response has not been defined.[1]

The eggs secrete antigenic materials that induce a host granulomatous response by macrophages, lymphocytes, giant cells, and eosinophils. Over time, granulomas decrease in size and are replaced by fibrosis. Fibrosis along the portal vein triads of the liver (i.e., periportal fibrosis or pipestem fibrosis) in intestinal schistosomiasis can be complicated by portal hypertension. Liver function remains intact unless there is concurrent insult, such as alcoholic or viral hepatitis. As portal hypertension advances and collateral blood flow channels increase, eggs can be shunted to the lungs, which can result in granulomatous pulmonary arteritis leading to pulmonary hypertension.

In urogenital schistosomiasis (caused by *S. haematobium*), chronic fibrosis of the urinary tract can lead to obstructive uropathy and hydronephrosis. Urogenital schistosomiasis can be complicated by pyelonephritis, calculi, and squamous cell carcinoma. Female genital schistosomiasis is characterized by inflammatory lesions of the genital tract, especially cervix, fallopian tubes, and vagina, including characteristic sandy patches associated with inflammation of the vaginal mucosa.[9]

Organs less commonly involved include skin, lungs, seminal vesicles, and central nervous system. *S haematobium* is associated with hematospermia (associated with seminal vesicle involvement) in males. Genital schistosomiasis in men and women can enhance transmission of human immunodeficiency virus (HIV) infection. *S. haematobium* also is associated with human papillomavirus (HPV) infection and infertility.[9]

Granulomatous reaction around ectopic eggs in the brain most often results from *S. japonicum* infection. Ectopic eggs in the spinal cord can cause transverse myelitis.[1,10]

Clinical Features

Acute Schistosomiasis

An acute febrile illness resembling serum sickness can occur 4 to 7 weeks after the initial infection, concurrent with maturation of female worms and the first egg release. This syndrome has been named Katayama fever, after a village in Japan where the entity was first described in association with *S. japonicum* infections. Common signs and symptoms are sudden-onset fever, cough, abdominal pain, headache, lymphadenopathy, and mild hepatosplenomegaly. In contrast to chronic schistosomiasis, peripheral eosinophilia is prominent in acute schistosomiasis.[1,8]

Intestinal and Hepatosplenic Disease

Patients with intestinal schistosomiasis (*S. mansoni, S. japonicum, S. intercalatum,* and *S. mekongi* infections) can be asymptomatic, or they can have crampy abdominal pain, diarrhea, bloody stools, or colonic polyposis. Physical examination commonly reveals an enlarged, nontender liver and an enlarged spleen.

End-stage disease consists of portal hypertension, ascites, and portosystemic varices with an absence of jaundice. Esophageal varices can result in severe bleeding and death.

Urogenital Tract Disease

S. haematobium infections can cause microscopic or gross (often terminal) hematuria. In some endemic areas where transmission is intense, hematuria is so common among boys that it is considered a normal passage to manhood, locally described as male menstruation.[11] Other complaints can include dysuria and urinary frequency. Patients with obstructive uropathy or chronic or recurrent pyelonephritis can have hypertension or end-stage renal disease. Adults can have a suprapubic mass or urinary obstruction from squamous cell carcinoma of the bladder.

Growth and Development

Children, even those with modest and low intensity of infection, may have depressed growth and cognitive development.[11–14] Schistosomiasis causes anemia. Physical findings in heavily infected children can include pallor and exercise intolerance.[14]

Diagnosis

The history should focus on whether the person has been in an area endemic for schistosomiasis and has had contact with open and likely contaminated freshwater ponds, lakes, or streams. Ocean beaches and chlorinated swimming pools are not sources of infection. Depending on the stage of illness, the physical examination can show rash, fever, and hepatosplenomegaly. Eosinophilia characterizes acute schistosomiasis. People infected with *S. haematobium* can have hematuria.

A diagnosis is made by identifying distinctive eggs by microscopy of stool or urine specimens (Fig. 285.2). *S. mansoni* eggs are oval (measuring 60 × 150 μm) and have a distinctive lateral spine. *S. haematobium* and *S. intercalatum* eggs are a similar size and shape, but they have a large terminal spine. *S. japonicum* and *S. mekongi* eggs are smaller (75 μm) and round with small, inconspicuous spines.[3] The miracidia can be seen in living mature eggs.

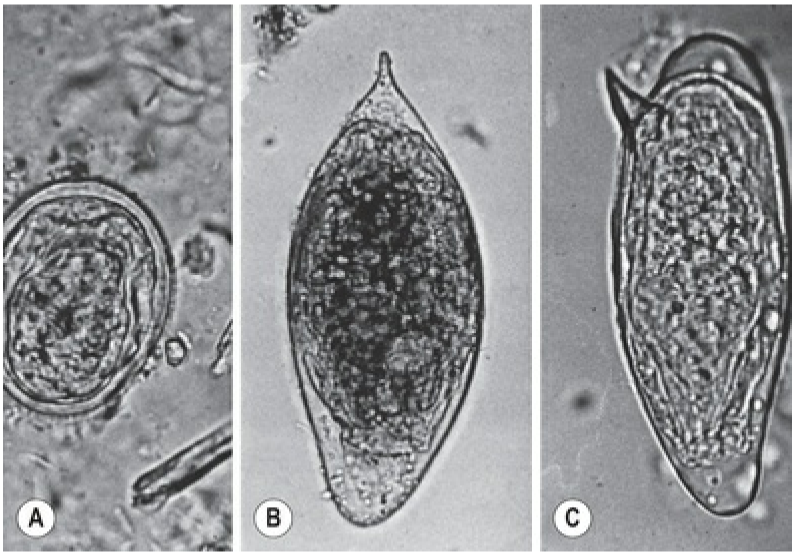

FIGURE 285.2 Ova of *Schistosoma japonicum* (A), *S. haematobium* (B), and *S. mansoni* (C) in stool or urine.

A stool concentration technique (1-g fecal sample) or a Kato-Katz preparation (20- or 50-mg fecal sample) optimizes microscopic diagnosis. The sediment of at least 10 mL of urine should be examined for *S. haematobium* eggs; the optimal sample to examine is a midday, terminal urine specimen. Examining multiple samples collected on separate days increases the sensitivity of diagnostic testing based on microscopy. Some infections have been diagnosed by identification of viable ova in histologic examination of rectal biopsy samples.

Microscopic examination can be negative for patients with acute schistosomiasis or light-intensity infections, and serologic testing is more useful for these people. Antibody detection can be used to screen ecotourists, missionaries, and Peace Corps volunteers who have had freshwater exposure in endemic areas. Several specialty laboratories offer serologic testing for diagnosis of schistosomiasis; for patients with a complicated exposure history, species-specific antibody assays are available through the Centers for Disease Control and Prevention (phone: 404-718-4745).[3] Travelers with positive antibody results are treated presumptively with praziquantel, but serology cannot be used to monitor the success of treatment.[15] Interpretation of antibody test results is more difficult for patients who originate from endemic areas because parasite-specific antibody persists for years despite successful treatment.[15] A new test for the detection of antigen in urine appears to be useful for screening for *S. mansoni* infection in the setting of control programs, but its utility for patient diagnosis is not defined.[16]

Ultrasonography is useful for staging chronic schistosomiasis.[1,17] In cases of intestinal schistosomiasis, ultrasound can be used to describe characteristic hepatic findings and the degree of portal hypertension and splenomegaly. In cases of urinary schistosomiasis, ultrasound can show bladder wall thickening, dilation of the ureter and renal pelvis, and bladder calculi. Abdominal imaging can show bladder calcification in *S. haematobium* infections.

Management

Praziquantel is the drug of choice for therapy[1] (see Chapter 296, Appendix 296.1). For *S. mansoni* and *S. haematobium* infection, 40 mg/kg of praziquantel in 2 divided doses taken orally for 1 day is recommended. For *S. japonicum* infection, 60 mg/kg in 3 divided doses for 1 day is recommended. Side effects of praziquantel typically are mild, abdominal pain is most common in treatment of intestinal schistosomiasis, and severity correlates with the burden of infection.

Praziquantel results in parasitologic cure in approximately 80% of cases, but in people who are not cured, the egg burden is reduced by 95% to 99%. The efficacy of praziquantel treatment depends on a robust host immune response to the adult worms.[1] Oxamniquine is an alternative drug for *S. mansoni* that is used primarily in South America. Oxamniquine is not available in the United States.

Praziquantel is the primary drug periodically used in school-based or community-based mass treatment programs to reduce the egg burdens of infected people.[2] Treatment of children and young adults promptly results in reversal of much of the disease, cessation of hematuria in urinary schistosomiasis, and regression of hepatosplenomegaly in intestinal disease. Antiparasitic treatment does not reverse chronic fibrotic organ damage, and the prognosis is guarded for people with portal hypertension, esophageal varices, and hydronephrosis.

Prophylaxis with praziquantel shortly after water exposure is not effective because developing schistosomula are relatively resistant. Artemisinins (antimalarial drugs) appear to be effective against developing stages and may be useful when the timing of exposure is known.[1,18]

Special Considerations

Central nervous system schistosomiasis results from ectopic egg deposition after aberrant migration of adult worms to the venules draining the brain or spinal cord. The ensuing granulomatous inflammation gives rise to serious manifestations that include seizures, headache, and signs of transverse myelitis such as paralysis, lack of sensation, and bladder incontinence. Previously unexposed people (i.e., immunologically naïve) may be at greater risk for these presentations. Use of corticosteroids or extended courses of praziquantel, or both, in these patients is controversial.[8]

Cercarial dermatitis (i.e., swimmer's itch) is a pruritic macular, papular, or vesicular rash that occurs as a consequence of cercariae penetration of skin. Cercarial dermatitis can occur from exposure to animal (usually avian) schistosomes, often in countries nonendemic for human schistosomiasis, and after exposure to seawater and freshwater. The cercariae die in the skin, and the rash responds to symptomatic treatment and topical corticosteroids.

Prevention

People planning travel to regions where schistosomiasis may be endemic can consult the Centers for Disease Control and Prevention (CDC) travel health website for further information on endemic countries.[19] Travelers should avoid swimming, bathing, or wading in open freshwater in those areas.

Strategies for controlling schistosomiasis include mass chemotherapy, health education, behavioral modification, improved sewage and sanitation, and control of snails through environmental engineering or the use of molluscicides. Large-scale control programs using one or more of these strategies has had various degrees of success in several countries. Schistosomiasis was eliminated completely from Japan by environmental engineering and improved sanitation.[2] Despite prolonged use of mass praziquantel treatment in several country settings, there has been no broadly documented case of emergence of drug resistance.[1,2]

Active research for a vaccine is ongoing.[1]

Key Points

Characteristic Features of Schistosomiasis

Microbiology

- Caused by trematodes that reside in the venules of the intestinal tract (*Schistosoma mansoni* and *S. japonicum*) or surrounding the bladder (*S. haematobium*). Female worms lay eggs that exit the body in feces or urine.

- If deposited in freshwater, miracidia emerge from eggs and infect specific snails. Cercariae later released from infected snails penetrate intact human skin and establish the infection, completing the life cycle.

- Eggs retained in tissue cause granulomatous inflammation that damages host tissues; patients with a heavy worm load are at greatest risk of disease.

Epidemiology

- More than 230 million people in 76 countries in tropical and subtropical areas are infected, but 85% of infected people reside in Africa, where *S. mansoni* and *S. haematobium* are the most common species and often are co-endemic.

- Schistosomiasis occurs in areas with poor sanitation where infected people deposit feces or urine containing eggs directly into freshwater containing the appropriate snails. Other people are later infected or reinfected when these same water bodies are used for swimming, bathing, washing of clothes and utensils, or agricultural purposes.

Clinical Features

- An acute febrile illness resembling serum sickness can occur 4 to 7 weeks after the initial infection, concurrent with maturation of female worms and the first egg release (i.e., Katayama fever).

- *S. mansoni* and *S. japonicum* infections can cause crampy abdominal pain and an enlarged liver or spleen. End-stage disease can include portal hypertension, ascites, and portosystemic varices.

- *S. haematobium* infections can cause microscopic or gross hematuria, dysuria, and urinary frequency, and characteristic sandy patches in vaginal mucosa or the cervix. End-stage disease can include genital lesions, obstructive uropathy, and squamous cell carcinoma of the bladder.

- Even with light worm burdens, children may have depressed growth and learning ability and anemia.

- Dermatitis can occur within 72 hours of exposure to infected water as cercariae penetrate skin. Cercarial dermatitis (i.e., swimmer's itch) also is caused by animal (usually avian) schistosomes, occurring in countries nonendemic for human schistosomiasis and after exposure to seawater and freshwater.

Diagnosis

- Detection of eggs in stool or urine

- Serologic testing

Treatment

- Praziquantel

Collection and Processing of Clinical Specimens

Proper collection and handling of clinical specimens are critical aspects of laboratory medicine. No degree of laboratory expertise can correct the error of inappropriately collected and transported specimens.[1] Common problems include insufficient quantity, contamination, inappropriate transport media, and delay in transport to the laboratory. Dry swabs are commonly sent but are rarely adequate for survival and isolation of bacteria.

Transport media are designed to prevent drying, maintain a balanced physiochemical environment, and prevent oxidation and enzymatic destruction of the pathogen. They provide minimal nutrients. Some transport media contain antimicrobial agents that suppress normal or contaminating flora to enhance the isolation of a specific pathogen or pathogens.

Specimens for bacterial culture should not be stored for longer than 24 hours before processing. When specimens cannot be transported immediately to the laboratory, appropriate alternatives are available. Urine is refrigerated at 2°C to 8°C for up to 24 hours. Inoculated blood culture bottles can be held at room temperature for several hours, but every effort should be made to submit bottles to the laboratory as soon as possible. Specimens for isolation of *Neisseria gonorrhoeae* should be inoculated on specific media such as modified Thayer-Martin or NYC agar; preferably transported in a self-contained, CO_2-generating transport system as soon as possible to the laboratory; and immediately incubated at 35°C in 5% to 10% CO_2. Cerebrospinal fluid (CSF) is held and transported rapidly at room temperature or at 35°C to 37°C and never refrigerated. Table 286.1 summarizes specimen collection and the usefulness of common transport media. Recommended collection and transport methods, standard media, and routine methods for microbial isolation are shown in Table 286.2.

Collection Methods and Transport Media

Method	Use
COMMONLY USED SWABS	
Calcium alginate	Toxic to *Neisseria gonorrhoeae,* herpes simplex virus, ureaplasmas; useful for collection of chlamydiae
Cotton	Residual fatty acids inhibit bacteria and chlamydiae
Dacron	Useful for viruses, culture for *Streptococcus pyogenes*
Flocked	Useful for viruses, culture for *S. pyogenes*
TRANSPORT SYSTEMS FOR AEROBIC OR FACULTATIVE ORGANISMS	
Culturette	Rayon-tipped swab prevents drying, maintains pH
PATHOGEN-SPECIFIC SYSTEMS	
Anaerobic bacteria	Anaswab system, Port-A-Cul vial or swab, Bio-Bag environmental system, BD anaerobic specimen collector; aspirate of specimen with expression into vial is always preferred
Neisseria gonorrhoeae	Jemec, Gono-Pak agar systems, contain CO_2-generating tablet ($NaHCO_3$–citric acid tablet); inoculated agar placed in bag and incubated for 18–24 hours before transport

Transport Systems and Media Inoculated Routinely According to Source of Specimen

Specimen	Transport System	Routine Media
Blood	Blood culture vials; if *Neisseria meningitidis,* no SPS	BAP, proprietary culture systems[a]
Cerebrospinal fluid	Sterile screw-cap tube	BAP, CHOC (CO_2), THIO
Brain abscess	Anaerobic transport medium	BAP, CHOC (CO_2), EMB/MAC, BAP-ANA, THIO, MS
Feces	Sterile screw-cap container	BAP, EMB/MAC, CAMPY, HEK, selenite/GN broth, CIN, MAC-S
Rectal swab	Swab transport system	BAP, EMB/MAC, CAMPY, HEK, selenite/GN broth, CIN, MAC-S
Gastric lavage, duodenal aspirate	Sterile screw-cap container	BAP, EMB/MAC, PEA, BAP-ANA, THIO, MS
Biopsied tissue	Sterile screw-cap container with preservative-free 0.85% NaCl	BAP, EMB/MAC, PEA, BAP-ANA, THIO, MS; for lung tissue: no PEA, add CHOC (CO_2)
Conjunctival swab	Prepare smears, directly inoculate media	BAP, CHOC (CO_2), EMB/MAC, THIO, MS
Genital, anal swab	Swab transport, GC transport system	BAP, EMB/MAC, THIO, CNA, MTM, NYC
Sputum, BAL fluid	Sputum trap, sterile screw-cap container	No anaerobic cultures; BAP, CHOC (CO_2), EMB/MAC, MS
Lung aspirate, transtracheal aspirate	Anaerobic transport system or sterile screw-cap container	BAP, CHOC (CO_2), EMB/MAC, MS, BAP-ANA, THIO
Throat, nasal, nasopharyngeal swab	Swab transport system	Throat: BAP, SXT-BAP; CHOC (CO_2), EMB/MAC, MS
Tympanocentesis fluid, sinus aspirate	Sterile screw-cap tube or anaerobic transport system	BAP, CHOC (CO_2), EMB/MAC, MS, BAP-ANA, THIO
Pleural, peritoneal ascites fluid	Sterile screw-cap container or blood culture broth bottle; anaerobic transport system	BAP, CHOC (CO_2), EMB/MAC, MS, BAP-ANA, THIO
Urine	Sterile screw-cap container	BAP, EMB/MAC, PEA/CNA
Wound: superficial, deep	Sterile screw-cap container plus anaerobic transport system	BAP, EMB/MAC, PEA, MS; for deep biopsies, add BAP ANA; THIO

[a] Proprietary blood culture systems include VersaTREK (Thermo Scientific), BacT/ALERT (bioMérieux), and BACTEC (Becton Dickinson).

BAL, bronchoalveolar lavage; BAP, blood-agar plate; BAP-ANA, blood agar incubated anaerobically; CAMPY, Campylobacter blood agar; CHOC, enriched chocolate agar; CIN, cefsulodin-irgasan-novobiocin agar; CNA, colistin–nalidixic acid; EMB, eosin–methylene blue; GC, gonococcal; GN, gram-negative; HEK, Hektoen enteric agar; MAC, MacConkey medium; MAC-S, MacConkey-sorbitol agar; MS, mannitol salt agar; MTM, modified Thayer-Martin medium; NYC, New York City agar; PEA, phenylethyl alcohol; SPS, sodium polyanetholesulfonate; SXT agar, blood agar with trimethoprim-sulfamethoxazole; THIO, thioglycolate broth.

Three types of culture media are used: enriched, selective, and differential. Enriched media support the growth of many nonfastidious and fastidious bacteria. Examples include chocolate agar, sheep blood agar, and thioglycolate broth. Selective media permit selective growth of certain groups of bacteria while suppressing others. For example, sheep blood agar containing colistin and nalidixic acid supports the growth of many gram-positive organisms but inhibits virtually all gram-negative bacteria. Differential media assist in differentiating similar groups of bacteria. For example, MacConkey agar permits differentiation of lactose-fermenting (e.g., *Escherichia coli*) and lactose-nonfermenting (e.g., *Proteus* spp.) gram-negative bacilli. Tables 286.3 and 286.4 summarize media used for bacterial isolation.

TABLE 286.3

Commonly Used Culture Media

Medium	Type of Medium	Indicator or Inhibitor	Comments
Sheep blood agar, 5%	N	None	Growth of most medically significant bacteria; allows determination of hemolysis
Horse blood agar, 3%–5%	S, N	None	Incubated at 5% CO_2; enhances isolation of *Haemophilus*
MacConkey agar	S, D	Bile salts, crystal violet, lactose, neutral red	Selective agar for Enterobacteriaceae, some other gram-negative rods; differentiates lactose-fermenting and lactose-nonfermenting organisms
MacConkey-sorbitol agar	S, D	MacConkey, sorbitol	Detects *Escherichia coli* O157:H7
Phenylethyl alcohol agar	S	Phenylethyl alcohol	Inhibits gram-negative bacteria; supports gram-positive bacteria
Colistin–nalidixic acid agar	S	Colistin, nalidixic acid, blood agar	Inhibits gram-negative bacteria; supports gram-positive bacteria
Mannitol salt agar	S, D	NaCl, mannitol, phenol red	Selects for staphylococci
Selective enterococcal agar	S, D	Oxgall, esculin, sodium azide	Selects for enterococci
Hektoen enteric agar	S, D	Bile salts, ferric ammonium citrate, sodium thiosulfate, lactose, sucrose, salicin, bromthymol blue, fuchsin	Enhances isolation of Enterobacteriaceae, *Shigella,* and *Salmonella* spp.; H_2S production; differentiates lactose-fermenting and lactose-nonfermenting bacteria
Deoxycholate-citrate agar	S, D	Deoxycholate, sodium citrate, ferric citrate, lactose, neutral red	Selects for *Salmonella* and some *Shigella* spp.
Selenite broth	S	Selenium salts	Enrichment for *Salmonella;* inhibits normal flora

***Campylobacter* agar**	S	Amphotericin B, cephalothin, trimethoprim, vancomycin, polymyxin B	Isolation of *Campylobacter* spp.; inhibits normal flora
Chocolate agar	N	None	Enriched medium that supports the growth of most nonfastidious bacteria and some fastidious bacteria (e.g., *Haemophilus* spp. and *Neisseria* spp.)
Modified Thayer-Martin agar	S	Vancomycin, colistin, nystatin, trimethoprim	Selects for *N. gonorrhoeae, N. meningitidis;* inhibits normal flora
New York City agar	S	Vancomycin, colistin, amphotericin B, trimethoprim	Same as modified Thayer-Martin agar
Anaerobic blood agar	N	None	Growth of all anaerobic bacteria; should contain yeast extract, vitamin K, and hemin
***Salmonella-Shigella* agar**	S, D	Bile salts, brilliant green, ferric citrate, sodium citrate, sodium thiosulfate, lactose, neutral red	Selects for *Salmonella,* some *Shigella;* inhibits normal flora
***Legionella* medium**	S	Vancomycin, colistin, anisomycin	Selects for *Legionella* spp.
Bordet-Gengou agar, Regan-Lowe medium, Stainer-Scholte medium	S	Cephalexin	Selects for *Bordetella* spp.
Löwenstein-Jensen agar	S	None	Selects for *Mycobacterium* spp.
BC-selective agar	S	Phenol red, ticarcillin, polymyxin B	Selects for *Burkholderia cepacia*
Eosin–methylene blue agar	S, D	Eosin–methylene blue	Selects for gram-negative enteric bacilli
***Haemophilus* test medium**	N	Mueller-Hinton agar, hematin, NAD, yeast extract	Used for antimicrobial disk susceptibility testing of *Haemophilus* spp.
***Haemophilus* test broth**	N	Mueller-Hinton agar, hematin, NAD, yeast extract	Used for antimicrobial susceptibility testing of *Haemophilus* spp.

Streptococcus pyogenes	SXT agar (CO$_2$)
Leptospira spp.	Bovine serum albumin–Tween 80
Yersinia pestis	TSA, BAP, BHI agar, CHOC (O2)
Bacteroides spp.	TSA, BBE, laked blood with kanamycin, vancomycin
Fungi	Isolator (blood), biphasic BHI broth, IMA, SAB

BAP, blood-agar plate; BAP-AMP, blood agar with ampicillin (10 μg/mL); BAP-ANA, blood agar incubated anaerobically; BBE, *Bacteroides* bile-esculin agar; BCSA, *Burkholderia cepacia*–selective agar; BCYE, buffered charcoal–yeast extract; BHI, brain-heart infusion; CAMP-BAP, *Campylobacter* blood-agar plate; CCFA, cycloserinecefoxitin-fructose–egg yolk agar; CHOC, enriched chocolate agar; CIN agar, cefsulodin-irgasan-novobiocin medium; CNA, colistin–nalidixic acid agar; EMB, eosin–methylene blue; IMA, inhibitory mold agar (with gentamicin and chloramphenicol); LJ, Löwenstein-Jensen medium; MAC, MacConkey medium; MTM, modified Thayer-Martin medium; NYC, New York City agar; OFPBL, oxidative-fermentative base–polymyxin B–bacitracin-lactose medium; PEA, phenylethyl alcohol; SAB, Sabouraud dextrose agar; SS agar, *Salmonella-Shigella* agar; SXT, blood agar with trimethoprim-sulfamethoxazole; TCBS, thiosulfate-citrate–bile salts–sucrose agar; TSA, trypticase soy agar; XLD, xylose-lysine-deoxycholate agar.

Specimen-Specific Isolation Methods

Blood

Specimen Collection.

Many advances have been made to maximize the recovery of bacteria from blood and to minimize contamination with skin flora during specimen collection. Blood culture samples collected from venipuncture sites antisepsed with chlorhexidine gluconate and 70% isopropyl alcohol have lower contamination rates than from sites antisepsed with povidone-iodine.[2] Sites must be allowed to dry for at least 1 minute before venipuncture. Because of limited safety data, chlorhexidine is used cautiously in infants younger than 2 months of age. Instead, povidone-iodine is preferred in this age group.[3] In one study, the use of 1% chlorhexidine was found to be safe (in newborns ≥1500 g of body weight) and more effective in reducing contamination rates.[4] The rubber septa of blood culture bottles or tubes are disinfected using 70% isopropyl or ethyl alcohol.

The quantity of blood cultured and the proportion of blood to broth are important factors; a ratio of at least 1 : 5 is desirable.[5,6] Inadequate specimen volume is the leading cause of low blood culture sensitivity. Most blood culture broths contain an anticoagulant, sodium polyanetholesulfonate (SPS), ranging in concentration from 0.025% to 0.05%. It inhibits phagocytosis and the bactericidal activity of serum, inactivates complement, and neutralizes lysozymes and aminoglycosides. SPS can inhibit the growth of some microorganisms, including *Neisseria* spp., *Streptobacillus moniliformis,* and *Francisella tularensis.* An appropriate ratio of blood to broth volume dilutes SPS, decreasing the natural inhibitory factors, and it dilutes antimicrobial agents that were present in the patient's bloodstream.

Many older conventional blood culture systems were suboptimal for pediatric use because the 5- to 10-mL recommended blood volume was inappropriate for infants. The degree of bacteremia in children usually is quantitatively higher than in adults; 1 to 5 mL may be an adequate sample from children, whereas higher volumes may be needed from adults.[6] Adequate blood volume per bottle increases recovery yields and decreases time to detection. Table 286.5 shows recommended blood volumes according to body weight.

[a] These are the recommended volumes necessary for the optimal isolation of bacterial pathogens. If unable to obtain sufficient blood for both bottles, inject available blood into an aerobic bottle (i.e., Peds Plus/F or Plus Aerobic/F).

[b] Plus Aerobic/F and Plus Anaerobic/F are the recommended media for larger children, adolescents and adults.

Although a single sampling may be sufficient for many patients with bacteremia, multiple samples are appropriate in certain circumstances (e.g., suspected endocarditis, for which two or three samples are desirable). The total volume of blood is probably more important in this circumstance than the number of samples. At least two sets of cultures are helpful for children with indwelling intravascular catheters. Bottles should not be inoculated with more than the manufacturer's recommended volume.

After blood is inoculated into a broth bottle, rapid incubation is essential. Delays in insertion of bottles into automated, continuously monitored blood culture systems can delay detection of bacteremia.[7]

Media.

Advances in blood culture systems have increased the yield of blood cultures, reduced the time to organism recovery, and diminished the laboratory technologist's hands-on time. Some systems were developed to maximize recovery of fastidious organisms. These systems include the Isolator (Wampole), a manual blood culturing system that uses blood cell lysis and centrifugal concentration of microorganisms before direct plating of the microbial pellet, and the continuous-monitoring blood culture systems, including the VersaTREK (Thermo Scientific), BacT/ALERT (bioMérieux), and BACTEC (Becton Dickinson and Company) systems. For the latter three systems, several broth formulations are available, including media for the recovery of aerobic and anaerobic bacteria, mycobacteria, and fungi. No single system is optimal for recovery of all microorganisms.

The Isolator system consists of a sterile tube of two sizes (i.e., 1.5 and 10 mL) that contains saponin and SPS, which lyse red and white blood cells in the blood specimen and inactivate complement and immunoglobulins, respectively. Hemoglobin binds to SPS and prevents inhibition of bacteria.[8]

The larger tubes are centrifuged at 300 *g* for 30 minutes in a fixed-angle rotor. With the use of an Isostat press and specialized pipettes, the lysate is removed, and the microbial pellet is retrieved and inoculated directly onto agar media, which are incubated and examined daily for growth. Media can be selected to maximize the recovery of suspected pathogens.[9,10] Isolation of certain fungi also is enhanced. As little as 1 mL of blood is required, and direct plating allows quantification of bacteria.[11] Excess contamination can occur with this system, but careful handling and inoculation of agar within a biological safety cabinet decreases the likelihood.

Compared with conventional systems, BACTEC has demonstrated increased recovery of organisms and decreased time to detection, particularly for *Mycobacterium* spp. The BD BACTEC FX system is a continuous monitoring, noninvasive blood culture system that uses internal fluorescent CO_2 sensors to detect the metabolic activity of bacteria growing in the culture broth. BACTEC Plus Aerobic/F, Plus Anaerobic/F, and Peds Plus/F bottles contain resins that may decrease the effect of antibiotics. This system can assist clinicians in identifying an intravascular catheter-related infection by using differential time-to-positivity values to compare a positive culture result from an intravascular catheter site with one from a peripheral venipuncture site.[11]

BacT/ALERT and VersaTREK systems are two additional continuous monitoring blood culture systems. They can detect bacteremia and fungemia with a higher yield of recovery and a reduction in the time to detection compared with manual blood culture systems.

Incubation.

Older conventional broth bottles were incubated for 7 days. Bottles were inspected for macroscopic growth daily and subcultured blindly. Acridine orange staining was performed after 18 to 24 hours of incubation. With newer, automated systems, bottles are incubated at 35°C with constant agitation and continuous monitoring, usually for 5 days before reporting negative culture results.

Most pediatric pathogens are isolated within 72 hours of incubation. With the newer blood culture systems, most bacterial pathogens are detected within 48 hours.[12–15] Incubation for more than 5 days is not usually warranted except in certain situations (e.g., suspected fungi, *Bartonella henselae, Corynebacterium, Actinomyces*, *Brucella*).

Special Pathogens and Situations.

Clinicians must communicate the suspicion of brucellosis, tularemia, melioidosis, glanders, anthrax, plague, meningococcal sepsis/meningitis, and enteric fever to the laboratory so that enhanced precautions can be taken when manipulating these cultures. If brucellosis is suspected, the automated blood culture is held for a minimum of 5 but no more than 10 days. Subculture to a blood agar, chocolate agar, or *Brucella* agar with incubation in 5% to 10% CO_2 at 37°C for at least 72 hours is usually adequate for isolation of *Brucella* spp.

For the isolation of cell wall–deficient bacteria, hypertonic medium (i.e., containing 10% sucrose or mannitol) is required. Nutritionally deficient organisms such as *Abiotrophia* spp. should be suspected when organisms are evident on Gram stain but fail to grow when subcultured. Broth can be subcultured onto a blood-agar plate streaked with *Staphylococcus aureus,* or media can be supplemented with 0.001% pyridoxal hydrochloride and 0.05% to 0.1% L-cysteine. A pyridoxal-impregnated disk also can be used. Plates usually are incubated overnight at 35°C to 37°C in 5% to 10% CO_2. Although rare causes of bacteremia and endocarditis, the HACEK group of microorganisms—*Haemophilus parainfluenzae, Aggregatibacter aphrophilus, A. paraphrophilus, A. actinomycetemcomitans, Cardiobacterium* spp., *Eikenella corrodens,* and *Kingella kingae*—grow within the routine incubation period for automated blood culture systems.[16]

Special conditions are required for isolation of *Bartonella* spp. and should be performed only by laboratories familiar with culture and identification of this organism. The Isolator system is used, with subsequent inoculation onto media enriched with fresh blood (i.e., 5% rabbit blood), and it is incubated in CO_2 at 35°C to 37°C for 15 days.

Polymerase chain reaction (PCR)-based amplification of the 16S rRNA gene followed by sequencing of amplicons can detect bacteremia within hours of collecting blood specimens.[17] A multiplex blood PCR can detect gram-positive and gram-negative bacteria and fungi in samples from febrile, neutropenic patients.[18] PCR can diagnose and serotype pneumococcal bacteremic community-acquired pneumonia in children.[19] Among people with *S. aureus* bacteremia, PCR can identify patients with methicillin-susceptible *S. aureus,* permitting reductions in vancomycin use, hospital stays, and costs.[20] At the time of writing, there are no commercially available, Food and Drug Administration (FDA)–cleared in vitro diagnostic products for detection of pathogens directly from fresh blood specimens. However, newer technologies, including peptide–nucleic acid fluorescence in situ hybridization (PNA-FISH), multiplex nucleic acid amplification, nanoparticle probe technology, and mass spectrometry, enable microbiologists to rapidly identify many clinically significant bacterial and fungal pathogens and determine antimicrobial resistance mechanisms from positive blood culture broths.

Urine

Although clean-voided midstream urine is an acceptable specimen for culture for older children and adults, this specimen is difficult to procure from young children. Collection of urine by a bag fixed to the perineum is a poor substitute. In this population, catheterized specimens or specimens collected by suprapubic aspiration are preferred. Because the distal part of the urethra normally is colonized, quantitative culture is required.

A known volume of urine (i.e., 0.01 to 0.001 mL) is inoculated by means of a calibrated inoculating loop or pipette onto agar media to permit quantification of isolated colonies. Detection of 10^4 colony-forming units (CFU)/mL of a single bacterial isolate from a clean-voided midstream urine specimen (i.e., 10^2 CFU/mL from a specimen obtained by catheter) correlates with probable true urinary tract infection. Any bacterial growth from urine obtained by suprapubic aspiration is considered clinically relevant. A prolonged time in ambient temperature from collection to inoculation (i.e., 2 hours) without urine specimen preservation (e.g., BD Vacutainer C&S preservative tubes [boric acid, sodium formate, and sodium borate preservative]) is associated with a false-positive quantitative culture. Isolation of multiple organisms with low colony counts usually indicates contamination, except in special circumstances, such as an inability to concentrate or retain urine and obstructive uropathy.

Although rarely performed in modern clinical microbiology laboratories, Gram stain or acridine orange stain of unspun urine can provide an indication of urinary tract infection; visualization of two or more bacteria of the same type per high-power field indicates significant bacteriuria (i.e., 10^5 CFU/mL). However, in one study, Gram stain did not have clinical utility in making the diagnosis of urinary tract infection in children.[21]

Cerebrospinal Fluid

Specimen Collection and Processing.

CSF must be transported to the laboratory without delay because it is hypotonic, and bacterial and human cells can lyse (affecting the cell count and contributing to falsely abnormal biochemical analysis) or use glucose and therefore lower measured levels. At room temperature, cell counts decrease approximately 32% in 1 hour and 50% in 2 hours after collection.[22] Neutrophils are affected more than lymphocytes. Refrigeration can render fastidious bacteria nonviable. If delay is expected, samples are stored at room temperature or incubated at 35°C to 37°C to maximize isolation.

Routinely, CSF should be inoculated onto sheep blood agar, enriched chocolate agar, and enrichment broth (e.g., thioglycollate broth) and incubated for 4 days at 37°C in 5% to 10% CO_2. If the Gram stain result is positive but culture demonstrates no growth at 72 hours, the culture is held for an additional 4 days. The minimal volume acceptable for culture of fungi and *Mycobacterium* is 2 mL, but a volume of 10 to 15 mL is preferred.

Centrifugation by cytospinning (2000 rpm, 350 *g*) to maximize pellet formation of bacteria and cellular elements produces a yield on direct examination of CSF by Gram stain superior to that of unconcentrated samples. Leukocyte morphology is preserved, and examination of large numbers of cells improves the validity of the differential cell count. In one study, smears were positive for bacteria in 78% of samples when cytospinning was performed compared with 56% for unconcentrated samples.[23]

Gram stain demonstrates organisms in 75% to 90% of untreated patients with meningitis. Patients with *Streptococcus pneumoniae* and *Haemophilus influenzae* infection are more likely to have a positive Gram stain result (90% and 86%, respectively) than are those with *Neisseria meningitidis* (75%).[24] The yield of Gram staining correlates with the density of bacteria in CSF (i.e., positive in 97% of infections with $>10^5$ CFU/mL of bacteria and only 25% with $<10^3$ CFU/mL).[25] The yield of Gram staining decreases in patients receiving antimicrobial therapy, even orally.

Acridine orange, or 3,6-*bis*(dimethylamino) acridine staining, is a more sensitive technique than Gram stain for detecting bacteria. This is especially true for patients who have received antimicrobial therapy.[26,27]

PCR appears to be an ideal tool for the diagnosis of bacterial meningitis, especially in patients who have received antibiotics.[28,29] Many studies have demonstrated its clinical usefulness, with sensitivities similar to those of routine culture technology but with a shorter turnaround time.[30–32] PCR appears in some studies to have a higher sensitivity than bacterial culture. In one study, 16S rRNA gene PCR had an overall sensitivity of 93% and a specificity of 98%.[33] In 2016 the FDA cleared a multiplex PCR system, the FilmArray Meningitis/Encephalitis panel, for the detection of several bacterial, fungal, and viral CNS pathogens from CSF collected by lumbar puncture.

PCR technology also is being used in outbreak investigations. In one study, investigators were able to link three cases of *Streptococcus salivarius* bacterial meningitis to a healthcare provider.[34]

Bacterial antigen detection is usually not useful in the diagnosis and management of meningitis. Its value appears to be limited to patients whose Gram stain, CSF culture, and blood culture are negative; pretreated patients; and when lumbar puncture is postponed because of the severity of illness.[24,35] Although PCR appears to be a superior detection assay, in some countries with limited resources, the combination of culture, Gram stain, and antigen detection has demonstrated high sensitivity for identifying causative pathogens.[36]

Respiratory Tract

Specimen Collection.

Tables 286.1 and 286.2 highlight proper collection of respiratory tract specimens for bacterial isolation. Throat swab for the detection of *Streptococcus pyogenes* (i.e., group A *Streptococcus* [GAS]) is the most common respiratory tract specimen sent for culture. Proper collection of the sample (i.e., swab-sweeping one tonsillar surface, posterior pharyngeal wall, and opposite tonsillar surface while avoiding the tongue and saliva) affects the yield of the culture.

Rapid Tests for Group A *Streptococcus*.

Routine culture on agar requires 24 to 48 hours for results. Rapid detection assays for streptococcal antigen can yield results in 10 to 70 minutes. The specificity of various tests is 62% to 100%, but the sensitivity is lower.[37] Although initial studies performed in microbiology laboratories demonstrated high sensitivity, performance in other settings shows variable results. Results are influenced by the skill, experience, and expertise of the person obtaining the throat swab and performing the assay. In a community office-based study, the sensitivity of the office culture for GAS was higher than the rapid antigen-detection test (81% vs. 70%). Both tests have specificities greater than 97%.[38] Tests using optical immunoassay have consistently demonstrated sensitivities and specificities higher than other assays. The isolation of GAS on agar permits antimicrobial susceptibility testing for macrolide resistance.

A reflex-to-culture confirmation has been recommended for people with a negative rapid antigen test result. Because specificities are high, positive antigen tests do not need to be confirmed by culture.[39,40] Although sensitivity increases with the severity of illness, the sensitivity of the assay may not be high enough to avoid performance of a culture.[41]

Most methods that use DNA probes and PCR demonstrate high specificity and good sensitivity.[42,43] Unfortunately, many of these tests are difficult to perform and are not suitable as point-of-care tests. A rapid (~20 minutes) real-time PCR method, the cobas Liat PCR system (Roche Diagnostics), has been FDA approved for GAS diagnosis. Benefits of this system include a short time to detection and its ability to act as a stand-alone test. Confirmatory testing (i.e., culture or PCR) is unnecessary. A licensed loop-mediated isothermal amplification (LAMP) assay is rapid and easy to perform. LAMP can obviate the need for antigen and reflex culture testing.[44] Some technology can detect macrolide and clindamycin resistance.

Antigen detection assays have been used to detect GAS at extrapharyngeal sites in cases of pyogenic arthritis, cellulitis, and parapneumonic effusions. One kit demonstrated high sensitivity and specificity for detecting antigen at skin sites.[45] Antigen detection and PCR assays can enhance detection of respiratory pathogens in parapneumonic fluid.[46–48]

Special Specimens.

Tympanocentesis or sinus aspiration for culture is extremely useful in special situations, such as immunocompromised patients, patients with intracranial complications, and those who fail to respond to antimicrobial therapy. Data are conflicting regarding the validity of culture of the nasopharynx in predicting the pathogens of sinusitis and otitis media. Routine use is not indicated.

Collection of sputum from children with lower respiratory tract infections is difficult technically. Aspiration of deep pharyngeal or tracheal secretions (with a Leuken trap) is used by some physicians. Sputum is a valuable specimen from older children. Ten or more squamous epithelial cells per low-power field strongly suggest an oropharyngeal origin of collection, and 25 or more white blood cells per low-power field denotes an adequate specimen. Organism isolation at quantities of at least 10^4 CFU/mL can predict the pathogen of infection, as proved by biopsy.[49–51] Gram stain should be used to aid in the interpretation of isolates from culture.

Because transtracheal aspiration is technically difficult in children, it is seldom performed. Bronchoscopy and especially a quantitative bronchoalveolar lavage specimen or protected brush is useful in the diagnosis of *Pneumocystis jirovecii*, mycobacterial, fungal, and bacterial infections.

***Burkholderia cepacia*.**

Isolation of *B. cepacia* from the sputum of patients with cystic fibrosis requires the use of selective media. *B. cepacia*–selective agar (BCSA) or oxidative-fermentative base–polymyxin B–bacitracin-lactose (OFPBL) medium have been used.[52,53] BCSA may be superior to OFPBL.[53]

***Bordetella* Species.**

Diagnostic tests for *Bordetella* have various sensitivities, depending on the case definition, level of immunization, adequacy of collection and transport, and diagnostic method.[54,55] When properly performed, culture is superior to direct immunofluorescence assay of nasopharyngeal secretions. Cultures are more likely to be positive during the first 2 weeks of illness.[56] Serologic tests by enzyme immunoassay (EIA) (i.e., *B. pertussis*–specific immunoglobulin G) are sensitive but difficult to interpret and usually require acute and convalescent sera.

PCR assays may provide higher sensitivity with a quicker turnaround.[57–60] In people with symptoms for 2 or more weeks, PCR demonstrates a higher sensitivity than culture or direct fluorescent antigen (DFA) testing, although no method is optimal.[56,61,62] A combination of culture, serology, and PCR provides a greater sensitivity when performed on previously immunized ill patients with cough.[54,58] In many clinical laboratories, PCR targeting the repetitive elements IS481 and US1001 of *Bordetella pertussis* and *B. parapertussis*, respectively, is the test of choice, and fluorescent staining and culture are no longer performed. Standardization of PCR assays and false-positive results are problematic. The Centers for Disease Control and Prevention (CDC) recommendations for primers and test conditions are available at http://www.cdc.gov/pertussis/clinical/diagnostic-testing/index.html.

Synovial and Peritoneal Fluid

The use of blood culture systems for normally sterile fluids has increased the detection of significant pathogens.[63] Inoculation of synovial fluid and peritoneal fluid into blood culture bottles results in a higher recovery rate of bacteria than inoculation of conventional agar or broth.[64,65] In one study, *Kingella kingae* was detected exclusively in specimens of joint fluid inoculated into BACTEC bottles.[66] In another study, BacT/ALERT demonstrated high sensitivity.[67] However, PCR testing may become the test of choice for detection of *K. kingae*.[68]

For patients with spontaneous bacterial peritonitis, inoculation of peritoneal fluid into BACTEC bottles more than doubled the recovery of gram-negative bacteria.[69] Although none of the fluids inoculated into conventional media yielded streptococci or enterococci, 33% of those inoculated into BACTEC bottles grew these organisms. Similar findings have been demonstrated for patients with peritonitis complicating peritoneal dialysis.[70,71]

Special Pathogens

Clostridium difficile.

Laboratory diagnosis of *C. difficile* remains a challenge, and many different testing algorithms have been published. Most algorithms have used one or more of the following test methods: glutamate dehydrogenase (GDH) antigen to detect organisms, toxin A/B EIA, cytotoxin neutralization, toxigenic culture, or toxin gene PCR.[72] Toxigenic culture is complex to perform, and results take 2 to 7 days. PCR detection of the toxin B gene *(tcdB)* has the highest sensitivity and negative predictive value of available tests, and it has the quickest turnaround.[73–75]

PCR assays appear to be more sensitive than EIA in detecting *C. difficile* as a cause of nosocomial outbreaks, but they can overestimate clinical relavance.[76] GDH antigen assays are excellent screening tests for *C. difficile;* they have a high sensitivity and negative predictive value, and results usually are available in less than 24 hours. However, a positive result must be confirmed with a different method for detection of toxin-producing strains.[77] Although many laboratories are using toxin A/B EIAs alone, many published reports indicate that this test alone is not appropriate for toxigenic *C. difficile* detection. Testing should be performed on watery, loose, or unformed specimens only. Infants frequently can be colonized with toxin-producing strains of *C. difficile* without symptoms; testing is discouraged.[78]

Assays are being developed to detect hypervirulent strains of *C. difficile*, such as NAP1/O27/BI. Primers and probes are used to detect deletions of *tcdB*, *tcdC*, and *cdtB*.[79]

Helicobacter pylori.

Many tests are available for the diagnosis of *H. pylori*. Histologic examination of tissue stained with Warthin-Starry silver and hematoxylin and eosin stains is considered the gold standard.[80] For patients with suspected treatment failure and for whom antimicrobial susceptibility testing is desirable, isolation of the organism should be attempted. For culture, commercially available *Brucella* agar plates with 5% horse blood or brain-heart infusion (BHI) supplemented with 7% horse blood are preferred. Biopsy samples can be tested for *H. pylori* by testing for urease.

The ^{13}C-labeled urea breath test and serology are noninvasive diagnostic methods used especially in children. The breath test requires some degree of cooperation for 60 minutes. The assay is highly sensitive and specific.[81–83] An antigen assay performed on stool has replaced the urea breath test at many institutions.[84] Detection of specific antibodies may not differentiate acute from past infection, and detection of specific immunoglobulin M (IgM) antibody is not sufficiently sensitive to be useful.[85]

Although PCR may be a promising diagnostic tool for *H. pylori* infection, the rapid urease testing and histologic examination provide reliable, reproducible results. PCR allows for the detection of *H. pylori* and is a culture-independent test for clarithromycin resistance.[86] Rapid office-based technologies have been developed that may obviate the need for invasive procedures for tissue or use of the ^{13}C-labeled urea breath test.[87]

Antimicrobial Susceptibility Testing

A microorganism is considered to be susceptible to an antimicrobial agent if in vitro growth is inhibited at a concentration that is one fourth to one eighth of that achievable in the patient's blood using a usual dose of the agent. In vitro resistance strongly predicts clinical failure, but in vitro susceptibility does not ensure clinical efficacy.

Clinical isolates warrant testing if susceptibility cannot be predicted reliably a priori. The test results of certain antimicrobial agents are reported routinely, whereas other results are reported selectively to gain information about individual and community susceptibility patterns and to control inappropriate use of certain agents, limit cost, and inhibit the emergence of resistant bacteria.

Standard Media and Test Conditions

Several methods (e.g., minimal inhibitory concentration [MIC], disk diffusion, and commercial systems, each with advantages and limitations) and media have been developed for susceptibility testing, and standards have been set for interpretation of results. Methods and interpretation are pathogen and source specific. Mueller-Hinton (MH) medium is recommended for testing nonfastidious bacteria, including Enterobacteriaceae, *Pseudomonas aeruginosa,* and other non-Enterobacteriaceae, staphylococci, and enterococci. MH medium has good batch-to-batch reproducibility, is low in trimethoprim-sulfamethoxazole (TMP-SMX) and tetracycline inhibitors, and shows a good growth pattern; a large body of data and experience with its use exists.

Cation (i.e., calcium and magnesium) adjustments are necessary when testing certain organisms (*P. aeruginosa*) because the cation concentration affects the reliability of testing aminoglycosides, tetracycline, and colistin; excessive cation levels cause smaller and low levels cause larger zones of inhibition. Cation-adjusted (i.e., 20 to 25 mg/L of calcium and 10 to 12.5 mg/L of magnesium) MH broth typically is used for microdilution testing. A standardized concentration of organisms is 3 to 5 × 10^5 CFU/mL. Testing of β-lactam agents requires a strictly standardized inoculum (i.e., 5 × 10^5 CFU/mL for MIC and 10^8 CFU/mL for disk diffusion testing). An increased inoculum can falsely increase the MIC value.[88]

MH medium supplemented with 5% sheep blood is recommended for testing nonenterococcal streptococci, including *S. pneumoniae. N. gonorrhoeae* should be tested on GC agar base with 1% defined growth supplement and incubated in 5% CO_2 for 20 to 24 hours. *Haemophilus* test medium incubated at 35°C in 5% CO_2 is used for *Haemophilus;* it provides optical clarity, stability, and reproducibility and permits testing of susceptibility to TMP-SMX.

Media containing thymidine analogues such as blood or chocolate agar can interfere with the results of TMP-SMX testing. Blood-supplemented MH medium also can antagonize TMP-SMX.

Table 286.6 provides a summary of recommended media for susceptibility testing. Microdilution tests usually are incubated for 16 to 20 hours at 35°C in ambient air. Tables 286.7, 286.8, and 286.9 summarize MIC interpretative standards for commonly encountered pathogens.

[b] Following evaluation of PK-PD properties, limited clinical data, and MIC distributions that include carbapenemase-producing strains, breakpoints were revised in 2017. With implementation of new breakpoints as shown, additional testing of isolates for possible carbapenemase production need not be performed for clinical purposes.

Susceptibility Test Methods

Disk diffusion by the Kirby-Bauer method is a standardized technique for testing rapidly growing pathogens.[89] Briefly, a standardized inoculum (i.e., direct suspension of colonies to yield a standardized inoculum is acceptable) is swabbed onto the surface of MH agar (i.e., 150-mm plate diameter). Because reproducibility depends on the log growth phase of organisms, fresh subcultures are used. Filter paper disks impregnated with a standardized concentration of an antimicrobial agent are placed on the surface, and the size of the zone of inhibition around the disk is measured after overnight incubation. Specific incubation time ranges are outlined in the Clinical and Laboratory Standards Institute [CLSI] documents.

The broth microdilution assay is used commonly to determine MICs quantitatively.[90] MIC trays can be custom made in the laboratory or purchased commercially. Usually, five to eight concentrations of antibiotics representing therapeutically achievable ranges are tested against each organism, or one to three concentrations are used to determine activity at the breakpoint MIC. The latter allows only qualitative assessment of susceptibility; the exact MIC is unknown. Interpretation of these somewhat arbitrary standards must be made in the context of the organism, the likely site of infection, the density of the organism at the site, and the host's immunocompetence.

Automated instruments can provide results in 2 to 18 hours.[91]

Four automated systems commonly used in the United States are the bioMérieux VITEK Legacy or VITEK 2, the Beckman Coulter MicroScan WalkAway, the BD Phoenix, and the Trek Diagnostic Systems Sensititre. VITEK 2 provides susceptibility and identification as early as 2 hours after inoculation. Plastic reagent cards contain small wells or microcuvettes that allow simultaneous testing for many different antimicrobial agents. Growth is detected by means of a densitometer. It uses turbidimetrically determined kinetic measurements of growth to compute MIC values by regression analysis.

MicroScan uses substrates that release fluorophores after interaction with bacterial enzymes, a process resulting in increased fluorescence. A major disadvantage is that some bacteria fail to release fluorophores after growth.[92] To solve this problem, MicroScan has incorporated rapid, turbidimetric readers in the panels. Depending on the organism, results are available between 4.5 and 18 hours of incubation.

BD Phoenix can accommodate up to 100 panels simultaneously. An indicator is added to the broth of each isolate, and the redox indicator measures bacterial growth. Reliable results can be available after approximately 10 hours of incubation.[93]

Sensititre is customizable with a choice of completely automated, semi-automated, or manual equipment. The Sensititre ARIS 2X system has a 64-plate capacity and can perform a combination of 192 MIC, breakpoint, or identification tests on a single instrument.

Advantages of automated systems are that they can be connected to the laboratory information system, provide rapid test results, allow intralaboratory and interlaboratory standardization, are less labor intensive, and have the potential of artificial intelligence for data review.[91] Disadvantages also are noteworthy. Systems may be too restrictive for some laboratories. Panels and cards are formatted by the manufacturer with predetermined antimicrobial agents and concentrations that may not be discerning enough for many clinical situations. Custom-made panels and cards are costly. Systems are not appropriate for all organisms; unacceptable results (usually falsely susceptible test results) can occur for bacteria such as *P. aeruginosa, S. pneumoniae,* enterococci, *Stenotrophomonas maltophilia,* and coagulase-negative staphylococci.[92] The initial capital investment may be prohibitive for some facilities, and a backup system is always needed in case of system failure.[94,95] Data coming through the computer interface must be verified for accuracy. Quality control depends on the use of American Tissue Culture Collection organisms.

The E-test (bioMérieux) is a method that integrates disk diffusion and agar dilution to determine the MIC and provides accurate, reproducible quantitative results. E-test offers a simple method for testing of anaerobes and fastidious bacteria.[96–99] Briefly, an impervious inert strip carries a marked, continuous concentration gradient of a predefined antibiotic consisting of more than 15 twofold dilutions. After incubation on seeded agar, the MIC is read at the edge of the zone of inhibition as it intersects the strip. Agreement among disk diffusion, agar dilution, and broth microdilution approaches 95%.[100] E-test is especially useful for testing the susceptibility of *S. pneumoniae* to penicillin. Compared with microdilution, E-test classified all resistant and intermediately resistant strains appropriately.[101] The best results are obtained when the agar is incubated in CO_2.[102–104]

Pathogen- and Mechanism-Specific Testing

Staphylococcus aureus.

Testing of staphylococci for methicillin (oxacillin) resistance is best achieved by detection of the *mecA* gene by PCR or its product, penicillin-binding protein 2a (PBP2a) by latex agglutination.[105] Both tests demonstrate 100% correlation.[106] PCR for the *mecA* gene can detect methicillin-resistant *Staphylococcus aureus* (MRSA) rapidly and directly from positive blood culture bottles with high sensitivity and specificity.[107]

For smaller laboratories, a disk diffusion test using a cefoxitin disk is a simple and inexpensive method for detecting methicillin resistance. Disk diffusion is still useful in testing staphylococcal isolates because testing can be performed for TMP-SMX and other antimicrobial agents commonly used for treatment of MRSA that may not be available on automated system panels. Detection of inducible macrolide-lincosamide–streptogramin B resistance in MRSA isolates (i.e., D-test) is easily performed using disk diffusion.[108] Some automated systems, such as VITEK 2, can detect inducible clindamycin resistance. Disk diffusion is not reliable for detection of vancomycin resistance in staphylococci, and MIC testing should be performed. Any *S. aureus* isolate with a vancomycin MIC of 8 μg/mL or greater should be sent to a reference laboratory.

***Streptococcus pneumoniae*.**

S. pneumoniae isolated from a sterile body site (i.e., blood, bone, or CSF) or other significant specimen (i.e., pleural or mastoid fluid) should be tested directly for MICs. Testing for penicillin, cefotaxime or ceftriaxone, meropenem, and vancomycin should be performed routinely. An oxacillin disk (i.e., 1-μg disk on MH blood agar) can be used as a screening test for β-lactam resistance of *S. pneumoniae* in laboratories that cannot perform MIC testing. Penicillin and appropriate β-lactam MIC tests must be performed on any isolate with a zone diameter of at least 19 mm to determine whether the isolate is resistant.

The CLSI has different interpretative criteria for meningitis and nonmeningitis pneumococcal strains for penicillin, cefotaxime, and ceftriaxone and different criteria for oral penicillin (see Table 286.9). Only meningitis interpretations are reported for CSF isolates, but all interpretations are reported for isolates from other sources.

Extended-Spectrum β-Lactamase and Carbapenemase.

In 2010, the CLSI changed its recommendations for testing cephems in Enterobacteriaceae. Previous guidelines recommended specific screening and confirmatory tests for detection of extended-spectrum β-lactamases (ESBLs) produced by certain strains of *Klebsiella* species, *Escherichia coli,* and *Proteus mirabilis,* which have been responsible for treatment failures with extended-spectrum cephalosporins. ESBLs also have been detected in isolates of *Salmonella, P. aeruginosa, Enterobacter,* and *Citrobacter* but are difficult to differentiate from chromosomal *ampC* β-lactamases that are normally found in these isolates. The new CLSI guidelines lower the interpretative standards for cephems, which allow a laboratory to report individual drug results without having to perform the supplemental ESBL screening and confirmatory tests. Unfortunately, many of the commercial systems do not test MIC ranges low enough to use these new standards. For these laboratories, isolates can be detected by testing ESBL-specific screening drugs and then confirming testing using cefotaxime and ceftazidime with and without a β-lactamase inhibitor (clavulanic acid).[109] ESBL-producing isolates are resistant to all penicillins, all cephalosporins, and aztreonam.

Detection of carbapenemase production in Enterobacteriaceae is challenging. The most common is the *K. pneumoniae* carbapenemase (KPC). Laboratories using disk diffusion should screen using an ertapenem or meropenem disk, and those using MIC methods can screen using any carbapenem. Isolates with meropenem MIC of 2-4 μg/mL can indicate carbapenemase production and should be confirmed using a modified Hodge test (MHT).[110] However, false detection of carbapenemase production has been observed with this assay.[111] With adoption of CLSI 2017 lowered breakpoints (see Table 286.7), additional testing need not be performed for clinical purposes. Clinical efficacy has not been determined for isolates that are MHT positive but test susceptible for any carbapenem. In these cases, laboratories should report only the MIC value without an interpretation and comment that the isolate is a carbapenemase producer. The treatment outcomes of infections caused by these organisms with a carbapenem, despite in vitro susceptibility, is unknown.

A test based on the in vitro hydrolysis of imipenem (i.e., Carba NP test) has been developed.[112] The Carba NP method is highly sensitive and specific, but it requires daily preparation of test reagents, and in one study, it failed to detect some Ambler Class D, OXA-type carbapenemases.[113]

β-Lactamase.

β-Lactamase production is the most frequent mechanism of resistance of *Haemophilus* species. Ampicillin resistance mediated by an alteration in protein binding is relatively uncommon and requires MIC or disk diffusion testing for detection.

Routine testing of *N. gonorrhoeae* isolates is limited to detection of β-lactamase. Other testing should be referred to a specialized laboratory.[114]

Three methods for detection of β-lactamase are available; the cephalosporin (nitrocefin) method is the most reliable. After inoculation onto a filter paper impregnated with nitrocefin, a color change to red denotes β-lactamase hydrolysis of amide bonds. This method detects most β-lactamases from important isolates such as *Haemophilus, N. gonorrhoeae, Moraxella, Enterococcus faecalis,* and *Bacteroides.* Other assays fail to detect all β-lactamases, and their specificity can be inferior to the nitrocefin assay.[115–117]

Enterococci.

Testing of enterococci for high-level resistance to gentamicin and streptomycin is useful to predict synergistic bacterial killing in combination with a β-lactam or vancomycin. Gentamicin- and streptomycin-containing agar or MIC wells (i.e., 500 μg of gentamicin and 2000 μg of streptomycin) are used to detect resistance to high levels of gentamicin or streptomycin. If high-level resistance to gentamicin is detected, resistance to other aminoglycosides is predictable. High-level resistance to streptomycin is specific only to this agent. Incubation for a full 24 hours is necessary (48 hours for streptomycin).

Many susceptibility testing methods have problems in detecting low-level vancomycin resistance among enterococci. An agar dilution plate with BHI agar containing 6 μg/mL of vancomycin (i.e., vancomycin agar screen plate) is highly sensitive and specific.[118] However, disk diffusion testing with incubation for at least 24 hours and even broth susceptibility test systems such as VITEK 2 are comparable in their capability to detect resistance.[119] Newer molecular tests such as LC *vanA/van B* detection assay (LC assay, Roche Diagnostics) and the GeneOhm vanR assay (BD Diagnostics-GeneOhm) are capable of detecting glycopeptide resistance genes (especially *vanA* genes) among enterococcal isolates.[105]

Fastidious Bacteria.

Many organisms can cause serious infections for which test methods are not standardized and interpretative guidelines are not available. Among these are *Corynebacterium* spp., *Bacillus* spp., *Listeria monocytogenes, Erysipelothrix rhusiopathiae,* miscellaneous gram-positive cocci such as *Leuconostoc* and *Pediococcus, Aeromonas* spp., *Campylobacter* spp., *Pasteurella* spp., the HACEK group of gram-negative bacilli, and others.[120,121] CLSI document M45-A addresses in vitro susceptibility methods and interpretative criteria for these organisms.[120] Susceptibility testing of anaerobic bacteria requires special qualifications.[122] Testing is indicated for failure of the usual therapeutic regimens or the presence of severe infection when long-term therapy is anticipated (e.g., brain abscesses).

Agar dilution testing is the referenced standard for determination of MICs. *Brucella* blood agar supports the growth of all anaerobic bacteria. Preparation of agar dilution assays is tedious and is not performed in many laboratories. The E-test method is used more widely. The agar disk diffusion and broth disk elution methods are not recommended because of poor correlation with the agar dilution method. Nitrocefin testing predicts only resistance to ampicillin and penicillin.

Testing of fastidious bacteria should be limited to a few specialized laboratories. Broth microdilution can be used for testing of *Nocardia*, but this testing is not standardized.

Mycobacteria.

An agar dilution test has been the standard for testing mycobacteria. A standardized concentration of test organism is inoculated onto agar (i.e., Middlebrook 7H10) containing the antimicrobial agent to be tested. After incubation for up to 3 weeks (35°C in CO_2), susceptibility is determined by comparing growth on the antibiotic-containing medium with that on antibiotic-free medium.

The BACTEC 460TB radiometric system has provided a major advance in the susceptibility testing of slow-growing *Mycobacterium* spp. BACTEC 12B or Middlebrook 7H12 broth containing an antimicrobial agent is inoculated with the test organism and incubated for 5 days at 37°C. The growth index is compared with that of a control bottle containing no antimicrobial agent.[123] Automated nonradiometric systems such as BACTEC MGIT 960 and VersaTREK appear to be as reliable as older methods.[124–127]

Antigen Detection Assays

Bacterial antigen detection assays, which were developed for rapid diagnosis, unfortunately have poor sensitivity and specificity, and their use is not recommended.[128,129] However, a urinary antigen detection assay (i.e., EIA) for *Legionella pneumophila* serogroup 1 is sensitive and highly specific.[130] An immunochromatographic assay is available. The sensitivity of the assay is higher than that of the EIA test, and results are available within 15 minutes.[131]

When access to PCR technology is not readily available, antigen detection assays have been suggested for the diagnosis of blood culture–negative pneumococcal pneumonia. The sensitivity of this serotype-specific tube latex agglutination assay on urine was 57% for serogroups included in the assay, and the specificity was 98%.[132] The urine pneumococcal rapid immunochromatographic antigen assay (Binax NOW, Binax) has high sensitivity in patients with pneumococcal bacteremia (95%), lobar pneumonia (76%), and bacteremic pneumonia (88%).[133] In children with parapneumonic effusions, the sensitivity and specificity of the assay were 88% and 71%, respectively.[134] For adults with community-acquired pneumonia, a positive urine test permits optimization of antimicrobial therapy.[135] False-positive test results were observed for 15% of febrile children with no identifiable pneumococcal infection probably due to nasopharyngeal colonization.[136] Real-time PCR performed on culture-negative parapneumonic fluid samples has substantially increased confirmation of *S. pneumoniae* infection.[47]

Fungi

Collection and Processing of Clinical Specimens

Specimens submitted for fungal culture are inoculated onto primary isolation media as soon as possible to ensure a high yield of recovery. If a delay is anticipated, the specimen can be stored in the refrigerator at 4°C. Blood and CSF are stored at room temperature or 30°C, and dermatologic specimens such as nail scrapings or hair clippings are stored at 15°C to 30°C. Respiratory specimens should be processed fresh.

The Isolator system is the preferred method for recovery of fungi from blood.[1,137] Although this is true for molds, the automated blood culture systems can detect the growth of most *Candida* isolates. It is important to add a small amount of 0.85% saline to a tissue specimen to prevent desiccation. Specimens can then be stored at 4°C for up to 8 hours. Bone marrow should be submitted in a 1.5-mL Isolator tube.

Nails, hair, skin scrapings, fluids, exudates, and biopsy samples for direct microscopic examination can be prepared with 10% potassium hydroxide (with warming of the sample to accelerate the dissolution process). Most samples also can be examined by fluorescent microscopy with 0.1% Calcofluor white stain, a substance that binds to the chitin and cellulose of cell walls and causes bright fluorescence. Giemsa and Wright stains of blood or bone marrow specimens can reveal intracellular yeast forms such as *Histoplasma capsulatum.* Cryptococcal antigen testing of CSF has replaced India ink staining.

Isolation and Identification

No single medium is appropriate for all specimens. Sabouraud dextrose and potato flake agars are frequently used fungal media. The glucose concentration usually is limited to 2.5%; higher concentrations can inhibit some fungi such as *Blastomyces dermatitidis.* To minimize the growth of saprophytes, antimicrobial agents such as gentamicin, chloramphenicol, and cycloheximide, are added to media. Inhibitory mold agar (IMA) is one such medium that has a higher and more rapid yield.

Agar plates usually are taped or wrapped in paraffin film, and mold cultures are opened only in a biological safety cabinet to minimize the possibility of dispersing infectious conidia throughout the laboratory. Media in tubes provide maximal safety and prevent dehydration and contamination. For fluid specimens, large volumes (>2.0 mL) should be obtained and concentrated through centrifugation at 1500 to 2000 *g* for at least 10 minutes. Tissues are minced and homogenized. Mycosel medium (Becton Dickinson), which consists of soybean meal digest, dextrose, chloramphenicol, and cycloheximide, is recommended for isolation of dimorphic fungi and dermatophytes. BHI agar containing gentamicin and chloramphenicol in addition to 10% sheep blood is recommended for isolation of *Cryptococcus neoformans* from potentially contaminated fluids such as sputum. Blood obtained in Isolator tubes should be inoculated onto chocolate agar, BHI, and IMA.

After isolation, filamentous fungi frequently are identified by the microscopic characteristics of their conidia-bearing apparatus, conidiation pattern, conidial morphology, and other structures. Cellophane tape preparations of mycelium are immersed in lactophenol cotton blue stain, coverslipped, and examined microscopically. The germ tube test, in which yeast are incubated for 2 to 3 hours at 35°C in fresh fetal calf serum, identifies *Candida albicans* by outgrowth of a tube (but not all *C. albicans* are germ tube positive).

The advent of DNA probes that can confirm the identification of *B. dermatitidis* and *H. capsulatum* has rendered obsolete previous temperature conversion studies of yeast-to-mold forms to confirm *Histoplasma*, *Blastomyces*, and *Sporothrix* isolates. A DNA probe is available to confirm the identification of *Coccidioides* spp. (i.e., *C. immitis* and *C. posadasii*), obviating the need to perform exoantigen testing and spherule production studies, the latter of which is extremely hazardous and very difficult to perform in the laboratory.

Commercial systems can be used to identify many types of yeast by assimilation of carbohydrates for growth. A commonly used system is API 20C yeast identification system. It is easy to use but does not include rhamnose and urea; the former is necessary for the identification of *C. lusitaniae*. Other frequently used systems are BBL Minitek, bioMérieux VITEK 2, MicroScan, and BD Phoenix, and mass spectrometry.

Antigen Detection

An antigen detection latex agglutination test for *C. neoformans* is available commercially and has been a highly useful clinical tool. However, laboratory personnel should be aware that disinfectants and soaps used to clean ring slides can cause false-positive test results.[138]

Immunoassays performed on urine (also CSF and blood) can detect *H. capsulatum* and *B. dermatitidis* antigens. These tests are particularly useful in the diagnosis of young infants and immunocompromised hosts with disseminated disease.[139–141] Antigenemia and antigenuria can be detected in acute pulmonary histoplasmosis; but they are detected infrequently in people with chronic pulmonary disease.[142] Caution in interpreting results is merited because of cross-reactivity between fungi. However, this sometimes can be used as a convenient diagnostic tool. In the southwestern United States, a positive *Histoplasma* antigen test can aid in the diagnosis of coccidioidomycosis.[143] The diagnosis of pulmonary histoplasmosis and blastomycosis can be made by the detection of antigen in bronchoalveolar lavage fluid. In one study, the overall sensitivity and specificity was 92% and 98.2%, respectively.[144]

Circulating *Aspergillus* galactomannan antigen can be detected in blood specimens from patients with suspected invasive aspergillosis. Frequent screening with this assay may lead to an earlier diagnosis for many immunocompromised patients.[145,146] Interpretation of positive test results requires careful consideration for patients receiving antibiotic therapy containing β-lactamase inhibitors such as piperacillin-tazobactam because false-positive results have been reported.[147] However, some investigators found that most commercial brands of piperacillin/tazobactam were not responsible for false-positive results.[148] Clinicians should be cautious in interpreting negative results because antifungal therapy appears to decrease test sensitivity.[149]

Bronchoalveolar lavage galactomannan testing has led to the diagnosis of invasive pulmonary aspergillosis in solid-organ transplant recipients and patients with hematologic diseases.[140,150] However, false-positive results can occur for lung transplant recipients.[140] False-positive galactomannan assays have been reported for patients with histoplasmosis.[151]

Antifungal Susceptibility Testing

The emergence of resistance in clinically relevant fungi and yeasts and the availability of new antifungal agents have resulted in the need for standardized methods for antifungal susceptibility testing and interpretation of results.[152–154] Advances in standardization and guidelines for interpretation permit testing of some types of yeast, but MIC testing of molds should be performed in reference laboratories. Yeast susceptibility can be performed using disk diffusion (i.e., *Candida* species only; see CLSI document M44-A2)[152] or broth dilution (i.e., see CLSI document M27-A3).[154] Unique problems are a slow growth rate and dimorphism.

The end point MIC for amphotericin B is easily defined, but end points for azoles are difficult to determine because of their unique partial inhibition of fungi. Use of the test medium RPMI 1640 with L-glutamine shows the best reproducibility for broth dilution methods. The technical aspects of testing must be controlled carefully to permit reproducibility and to avoid inaccuracies. Few data exist that enable correlation of test results with clinical outcomes.[152–154]

Availability of echinocandins and voriconazole increase the options for more effective treatment of infections such as aspergillosis. Combinations of these agents may be desirable in some patients because of their synergistic effects.[155] Susceptibility and interactions are not always predictable. Due to potential interlaboratory and intralaboratory reproducibility problems, testing of filamentous fungi and for effects of combination therapy should be limited to specialized laboratories.[156]

Parasites

Examination of Feces

Collection and Preservation

Proper collection and handling of stool specimens are critical for the detection of parasites. Stool should be collected in a clean, wide-mouthed container with a tightly fitting lid. Unpreserved stool specimens are considered potentially infectious and must be handled with care. Stool samples are rejected if they contain mineral oil, bismuth, or barium, which may interfere with accurate examination. The specimen should not be contaminated with urine or water from the toilet.

If transportation to the laboratory is not prompt, the specimen is stored in the refrigerator. Dry samples are not acceptable. A minimum of three samples over a period of 7 to 10 days usually is required for accurate testing. For the diagnosis of amebiasis and giardiasis, at least six specimens may be required before negative clinical interpretation is appropriate. In one study, only 72% of parasites were detected with a single specimen. Another 28% were identified with two additional specimens.[157] In areas of high parasite prevalence (20%), a comprehensive evaluation of a single specimen may have enough sensitivity to be appropriate clinically.

Liquid stool should be examined or preserved within 30 minutes of collection, soft or semiformed stool within 1 hour, and formed stool on the same day. Two commonly used preservatives are polyvinyl alcohol (PVA) and formalin. PVA provides a good permanent smear and preserves the integrity of trophozoites and cysts. PVA should be handled with care; the substance is poisonous. Formalin is a useful preservative in general, and formalin specimens can use a concentration procedure to increase parasite detection, especially cyst and helminth ova (trophozoites do not survive the concentration method). Formalin is superior for helminth ova, *Giardia,* and *Cystoisospora belli.*

Examination

Stools are examined grossly for consistency, mucus, blood, and adult worms or proglottids. Trophic amebae and flagellates are encountered more commonly in liquid and soft specimens; these organisms disintegrate rapidly at room temperature. Trophozoites and cyst forms are observed more commonly in semiformed stools, and cysts are seen in formed stools.

A direct wet mount smear can be prepared with 0.85% saline or with D'Antoni or Lugol iodine. The specimen is scanned at ×10 and then at ×40 magnification. Because wet mount requires fresh stool, it is done infrequently.

Concentration of feces is important when small amounts of organisms are expected. Concentration is designed to facilitate the recovery of protozoan cysts, coccidian oocysts, and helminth eggs and larvae. The flotation or sedimentation (i.e., formalin–ethyl acetate) method can be used. Flotation provides a cleaner sample than sedimentation; the higher density of zinc sulfate pushes the protozoan cysts to the surface after centrifugation. The cysts are recovered for examination from the supernatant. Helminth eggs are better recovered with the sedimentation method. After sedimentation, an iodine stain is performed.

A permanent stain smear is prepared for the identification of intestinal parasites using a PVA-preserved specimen. Wheatly-Gomori tissue trichrome and iron-hematoxylin stains are preferred.

Special Pathogens

Permanent staining with trichrome or iron-hematoxylin allows definition of morphology and provides a slide for reference. *Cryptosporidium* species usually are not seen with either stain; they require the use of stains for acid-fast bacilli, such as the modified Kinyoun stain. These stains also can be used to detect *C. belli* and *Cyclospora cayetanensis*. If the sediment is mucoid, potassium hydroxide should be added.

Monoclonal antibody assays or direct fluorescent antibody stains for *Giardia* and *Cryptosporidium* are useful when the density of parasites is expected to be low. In specialized laboratories, fecal culture methods or coprocultures (i.e., Baerman technique) can be used to recover parasites. These techniques are useful in cases of low-density infestation with hookworms, *Strongyloides,* and *Trichostrongylus.*

A simple way of obtaining larvae and adult worms of *Enterobius vermicularis* for examination is the cellulose tape method. Tape reversed on a tongue depressor is pressed against the anus in the early morning. The tape is then placed over a slide and examined for the characteristic D-shaped *E. vermicularis* eggs using light microscopy.

Stool antigen detection assays using polyspecific polyclonal antibody are nonspecific and less sensitive in transported or stored samples with fixatives. *Giardia* antigen GSA 65, which is specific to *G. lamblia* and stable in the gastrointestinal tract and in fixatives, is a potentially useful antigen. Detection with a *Giardia* antigen detection method (Prospec T/Giardia, Alexon) is sensitive and specific when testing symptomatic and asymptomatic people. The technique has a sensitivity of 96%, compared with 74% for stool examination for eggs and parasites.[158]

Other immunoassays can detect *Cryptosporidium* antigens.[159] They have good sensitivity and specificity, are easy to perform, have quick turnaround, and are reproducible.[160] Several multiplex, real-time PCR assays have been developed for the detection of *Entamoeba histolytica, G. intestinalis, Cryptosporidium* spp., and a few other protozoan parasites.[161]

Trichomonas vaginalis can be observed on direct saline wet mounts from vaginal secretions, first-voided urine, or other fluids such as respiratory tract secretions from neonates.

Detection of Gastric-Duodenal Pathogens

Duodenal contents can be examined for parasites and protozoa by means of the Enterotest capsule. A silicone rubber capsule that contains a spool of string attached to a weight is swallowed. The capsule dissolves, and by peristalsis, the string moves into the small intestine. The string provides an attachment site for duodenal mucus and *Strongyloides* larvae, *Giardia* trophozoites, cryptosporidia, and *Cystoisospora* oocysts. No food is allowed during the test, which takes approximately 4 hours. Yellow staining of the string indicates bile. Duodenal aspiration provides an alternative specimen, but the string test is less invasive.

Tissue Specimens

Tissue obtained by biopsy is the preferred specimen for severe parasitic infections such as toxoplasmosis. Impression smears, squash preparations, and scrapings from skin and nails are commonly submitted specimens. These specimens are stained and examined microscopically. Giemsa stain of the lung, small intestine, skin, or brain can reveal organisms such as *Toxoplasma gondii, Leishmania, Naegleria,* or *Entamoeba.* Other stains such as trichrome and methenamine silver enhance the visualization of parasites. Immunospecific stains such as the TYSGM-9 stain for *E. histolytica* have been developed to improve the sensitivity and specificity of direct microscopy. Modified acid-fast staining of the small intestine allows visualization of *Cryptosporidium parvum, C. belli,* and *C. cayetanensis.*

Blood Smears

Thin- and thick-film smears stained with Giemsa or Wright stains are still reliable and efficient ways of diagnosing bloodstream parasitic infections caused by *Plasmodium, Babesia, Trypanosoma,* and *Leishmania. Borrelia* spp. and *Yersinia pestis* also can be visualized with these stains. Parasites are observed more easily in the thinner portion of a thick film. The thick film should be examined for 5 to 10 minutes (~100 fields) and the thin film for 15 to 20 minutes (~300 fields).

A single blood sample is not sufficient to exclude a diagnosis of these parasitic diseases. Blood samples should be submitted every 6 to 12 hours. Anticoagulated blood with EDTA is acceptable only if the sample is less than 1 hour old. Buffy coat preparations can be stained to visualize the amastigotes of *Leishmania* within monocytes. Fingerstick blood is preferred when examining blood for *Plasmodium*. In one study, a rapid diagnostic test for malaria, the NOW Malaria Test (Binax), was superior in detecting *P. falciparum* (sensitivity of 100%) to a single set of blood smears.[162]

Newer diagnostic tests (e.g., PCR, loop-mediated isothermal amplification) are becoming more available worldwide.[163] They are valuable in areas in which microscopy is unavailable and where the availability of antimalarial agents is limited. In some instances, people testing negative do not require treatment.[164]

Rickettsiae

Rickettsial organisms are difficult and hazardous to isolate, and they are difficult to visualize with light microscopy. Immunofluorescent stain of biopsy samples is useful.

Most diagnoses are based on clinical features and confirmed with serologic tests.[165] The most commonly used tests are the indirect fluorescent assay and the microimmunofluorescent test. Additional assays have been developed. A latex agglutination test can detect IgM and IgG antibody against specific rickettsial antigens. Cross-reactions occur among rickettsial species. False-positive results with indirect fluorescent assays have been reported for users of illicit parenteral drugs. The Weil-Felix assay is rarely used because of its lack of sensitivity and specificity.

Immunoserology

Documentation of a specific immune response to a pathogenic microorganism provides proof of infection. Methods used for the measurement of antibodies include hemagglutination, EIA, latex agglutination, complement fixation, immunofluorescence, and neutralization assays. Certain methods may be better for certain infections.

The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin tests are the current screening tests for syphilis and for measures of the activity of infection. Observation of spirochetes in body fluids by dark-field examination (or by the direct fluorescent antibody test) or positive specific treponemal antibody tests such as the fluorescent treponemal antibody absorption test confirm infection.[166] The use of specific treponemal antigens enable more precise screening for syphilis. However, the antibody test may have poor positive predictive value in low-risk populations and cannot distinguish active from treated disease. Positive assays must be confirmed with nontreponemal assays.[167]

The immune response to specific pathogenic fungi as determined by immunodiffusion or completion fixation assays can assist in the diagnosis of *Aspergillus, Blastomyces, Histoplasma,* and *Coccidioides* infections. However, false-negative test results occur, especially early in the disease or in immunosuppressed hosts.[168]

Febrile agglutinin tests have limited clinical utility in developed countries. They should not be used.[169]

Newer Technologies

Genomics- and proteomics-based methods have revolutionized the ways in which infectious diseases are diagnosed. Nucleic acid amplification tests (NAATs), such as PCR and transcription-mediated amplification, have become important resources for the detection of pathogenic microorganisms and viruses directly from patient specimens. PCR, which is more sensitive than in situ hybridization methods, has proved useful for identifying slowly growing microorganisms such as *Mycobacterium tuberculosis*; difficult or impossible to cultivate pathogens, including *Borrelia burgdorferi, Rickettsia* spp., and many viruses; potential agents of bioterrorism; and multiple parasitic protozoa, including *Plasmodium* spp., *Giardia duodenalis*, and *Cryptosporidium* spp. The incorporation of DNA-intercalating dyes or fluorescent probes and high-resolution melting analysis into PCR has paved the way for real-time pathogen detection, identification, and quantification of target nucleic acids in clinical specimens, which allows determination of disease activity and response to therapy.

Multiplexing of real-time PCR permits detection of numerous analytes, which can include multiple genetic targets of one pathogen or numerous different pathogens in a single specimen. Multiplex assays are designed to detect a number of pathogens associated with specific diseases processes; these assays are referred to as *syndromic panels*. For the investigation of infectious disease outbreaks, molecular fingerprinting methods such as pulsed-field gel electrophoresis, multilocus sequence typing, multiple loci variable-number tandem repeat analysis, and next-generation sequencing have become standard in public health laboratories. Collectively, these methods have fostered the field of molecular epidemiology.

Mass Spectrometry.

Mass spectrometry has become commonplace in many clinical microbiology laboratories as an adjunct to or replacement for conventional phenotypic microbial identification methods. However, laboratories are cautioned against totally eliminating phenotypic methods because these methods will be needed when the mass spectrometer is being serviced or is otherwise out of commission, especially if another mass spectrometer is not available.

Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry enables rapid identification of bacteria, yeast, and molds quickly and accurately using growth from plate cultures.[170] MALDI-TOF mass spectrometry has been applied to the identification of microorganisms directly from positive blood culture broths. In addition to MALDI-TOF, PCR coupled with electrospray ionization (ESI) mass spectrometry offers a promising role in the identification of microorganisms and viruses.[171–173] Two manufacturers (i.e., Bruker Corporation and bioMérieux) market FDA-cleared MALDI-TOF systems for identification of microorganisms isolated in culture: the MALDI Biotyper system and the VITEK MS system, respectively. Research-use-only mass spectral profile (MSP) libraries also exist and can be validated by laboratories for use in diagnostics. Overall, MALDI-TOF has demonstrable superior performance compared with phenotypic methods for identification of bacteria, mycobacteria, and fungi. Emerging technologies are reviewed by Buchan and Ledeboer.[174]

Syndromic Panels.

Several diagnostic product manufacturers are developing or market multiplex nucleic acid–based assays for the detection of agents causing bloodstream, respiratory tract, gastrointestinal tract, and central nervous system infections. Assays have been developed based on multiplex nucleic acid amplification and high resolution melting analysis (e.g., FilmArray, BioFire Diagnostics, LLC), nanoparticle-laden antibody or oligonucleotide probes (e.g., Verigene System, Nanosphere, Inc.), and ferrocene-labeled oligonucleotide probes coupled with electrochemical detection (eSensor XT-8, GenMark Diagnostics, Inc.).

FDA-approved FilmArray panels are available for the analysis of positive blood culture broths (i.e., Blood Culture Identification Panel, which detects 24 pathogens and 3 antimicrobial resistance markers),[175] nasopharyngeal swabs (i.e., Respiratory Panel, which detects 17 viral and 3 bacterial pathogens),[176] and stool specimens (i.e., Gastrointestinal Panel, which detects 22 bacterial, parasitic, and viral pathogens).[177] A meningitis panel is being evaluated for the detection of 16 bacterial, fungal, and viral pathogens.

Viruses

The availability of rapid and reliable viral diagnostic tests, particularly nucleic acid amplification tests (NAATs), facilitates decision making in the prevention, treatment, public health, and infection control measures related to viral infections. With specific antiviral therapy available for many clinically relevant viruses, a specific viral diagnosis may limit the need for further diagnostic testing and unnecessary antibiotic therapy.[1–3]

Two major approaches to diagnosis of viral infection are virologic (detection of virus) and serologic (detection of antibody, antigen, or both). The virologic approach includes (1) isolation of infectious virus in cell culture, (2) detection of viral antigen by immunologic methods (e.g., fluorescent antibody [FA] testing or enzyme immunoassay [EIA]); (3) visualization of viral particles by electron microscopy (EM); and (4) detection of viral nucleic acid by molecular techniques (e.g., hybridization or NAATs). Cytologic examination of tissues and cells may identify viral effects, thus prompting further investigation. Occasionally, cytologic changes can be sufficiently specific to suggest a particular agent (e.g., cytomegalovirus [CMV]).[4] The serologic approach includes detection of the following: (1) virus-specific antibodies indicating recent, current, or past infection, as well as immunity following recovery or vaccination; (2) a significant rise in virus-specific immunoglobulin G (IgG) antibody suggestive of acute or recent infection; (3) virus-specific antigens (e.g., hepatitis B surface antigen [HBsAg]); or (4) virus-specific IgM antibody in late acute or early recovery phase sera. As the immune response matures following a viral infection, low-avidity IgG antibodies are replaced with high-avidity antibodies. EIAs capable of measuring the avidity of IgG antibodies to specific viruses have been used to distinguish primary from secondary (reactivation) antibody responses to vaccination or natural infection.[5,6]

Clinically, laboratory tests for the detection of virus infection can be divided into 3 specific categories: those used to (1) make a specific diagnosis, (2) measure virus activity in patients known to be infected (e.g., viral load testing for human immunodeficiency virus [HIV]), and (3) screen for infection or a carrier state (e.g., before transplantation or blood donation).
